Continental crustal growth in collision zones on the Northern Tibetan Plateau

HUANG, HUI

Continental crustal growth in collision zones on the Northern Tibetan Plateau

Hui Huang

A THESIS SUBMITTED IN PARTIAL FULFILMENT OF THE

REQUIREMENTS FOR THE DEGREE OF DOCTOR OF PHILOSOPHY

AT DURHAM UNIVERSITY

Department of Earth Sciences

Durham University

March 2014

“If you can’t explain it simply, you don’t understand it well enough.”

Albert Einstein

Abstract

The continental crustal growth has been a great interest to geoscientists and its importance is self-evident. Any models trying to reveal how it works must be able to explain 1) how the continental crust gains its andesitic bulk composition with juvenile isotope signatures; 2) how the volume of the crust increases episodically. Granitoids with the juvenile isotopic signatures in the collision zones provide the special insights into the nature of the continental crust and a unique opportunity to investigate the mechanism of crust growth. This thesis reports results from major and trace element data, whole rock Sr-Nd-Hf-Pb isotopic data, zircon geochronology and *in situ* Hf isotopes of granitoids as well as, if any, the enclosed mafic magmatic enclaves (MMEs) from the three ancient collision zones crossing the Northern Tibetan Plateau.

I-type granitoids and their MMEs from the East Kunlun Orogenic Belt (EK) in the Northern Tibetan Plateau are dated as 250 Ma years old. They are cal-alkaline in nature with compositions resembling the bulk continental crust (BCC). Whole rock Sr-Nd-Pb-Hf isotopes reveal that they are products of partial melting of the 'trapped' subducted oceanic crust at the onset of the collision and the MMEs are the aggregated early cumulates in the parental magma rather than the mafic endmember involved in the magma mixing as previously suggested.

I- and S-type granitoids from the Qilian Block (QB) further north in the Great Plateau are dated as 450 Ma. Their lithological and geochemical heterogeneity and isotopic changes with time are inferred to correspond to the collision. The abundant inherited zircons with ages as old as Archean reveal the presence of the Archean basement underneath the Qilian Block and indicate that the Qilian Block may have been a micro continent during its drift in the ancient ocean.

Granitoids and their enclosed cumulates from Kekeli Batholith further north in the plateau are 500 Ma years old. They have decoupled whole rock Nd and Hf isotopes and discrepancy between whole rock Hf and zircon *in situ* Hf isotopes. These inconsistences are understood to result from different mineral crystallization timings during mixing between endmembers with distinct isotopes. This highlights the need for detailed whole-rock or non-zircon phases Hf isotopic investigation in order to develop a comprehensive understanding of the granitoids of hybrid origin.

Declaration

I, Hui Huang, declare that this thesis, presented for the degree of Doctor of Philosophy at Durham University, is my own original research and has not been previously submitted to Durham University or any other institution except where reference is made to previously published or unpublished work.

Acknowledgements

The past 3 and half years were full of smiles, tears and memories. Here comes the moment to look over the journey past, appreciate and remember all the happiness that life has given. I offer my sincere gratitude to the following people, to only some of whom it is possible to mention here. It would never have been possible to complete this doctoral thesis without your great help and support.

First and foremost I would like to express my heartfelt thanks to my long-suffering supervisor Yaoling Niu, who is not only my adviser but dear friend. You are the source of academic knowledge and life enlightenment which has helped turn me into an independent thinker and a mature human being from a poorly educated naive person. I would not be where I am today without your continuous education and encouragement. I also owe a big thank you to my dear second supervisor Geoff Nowell for being a great guide with patience and inspiration throughout my difficult labbing time, instrumenting time and paper writing. Without the inputs and efforts squeezed out of your busy schedule this work would not have been efficient or possible. My previous supervisor Zhidan Zhao in China University of Geosciences (Beijing), I thank you for the precious advice at each turning point of my life. Thank you to Durham University and China Scholarship Council for providing the funding that has made all of this possible.

Thanks go to the Mark Allen, Pierre Bouilhol, Vali Memeti, Iain Neill, Jeroen van Hunen, Alex B.J., Valentina Magni, Dicheng Zhu, Shuguang Song, Li Su and Shuijiong Wang for your brilliant academic informations and suggestions which helped me overcome those difficulties. Thanks are owed to Chris Dale and Scot Dempsey for their kind help in the clean laboratories; Stuart Jones and Stephan Stricker for the mineral point counting; Shuo Ding, Huixin Hei, Lei Wu, Dong Liu, Li Su and Shuijiong Wang for sample collection, preparation, major and trace elements analyses and zircon *in situ* analyses. I extend further thanks to the editor of *Chemical Geology* Laurie Reisberg for her patient detailed constructive comments which significantly hone my painstaking first paper.

Special thanks go to my fellow grad students and department administrative/technical staff. In particular, thank you to Helen Foster, my dearest friend and best housemate, for always being there throughout my ups and downs. Life in a foreign country cannot be so great without you. Suize, Ute, Alex, Pete, Bansri, Jingxiu, Jing, Yang, Ang, Yuanyuan, Fran, Cui, Li, Salim, Stephan, Vale, Hongliang, Yi, Rachel, Simon, Chris, Lily, Roberto, Yan, Mark, Ian, Amelie and Andy, thank

you for your friendship and support during my time in Durham. And thank you to my friends in China and other corners of the world for the endless love.

Finally, thank you to Mom, Dad and Shuijiong for the warmest careness crossing the Eura-Asia continent and the Atlantic. Thank you for the support, understandings and forgiving my temporary absence.

Chapter 1: Introduction

1.1. Thesis Rationale

This thesis aims to investigate the processes through which continental crust grows in the ancient collisions on the Northern Tibetan Plateau. The significance of continental crust is self-evident, yet our understanding of its origin and evolution remains unsatisfactory and has been a major goal of Earth scientists for decades. Continental crust has andesitic bulk composition. Its arc-like geochemical signature characterized by enrichment in large ion lithophile elements (e.g., Rb, Cs, K, and especially Pb) and depletion in high field strength elements (e.g., Nb, Ta, and Ti) have led to the standard "island arc model" in which continental crust is produced through subduction-zone magmatism (Taylor, 1967, Taylor, 1977, Taylor and McLennan, 1985 and Rudnick and Gao, 2003). In spite of its popularity, this model fails to explain several basic observations (see Niu and O'Hara, 2009 and Niu et al., 2013). For example, bulk island arc rocks are basaltic (Arculus, 1981, Gill, 1981 and Pearcy et al., 1990) while the bulk continental crust is andesitic (Taylor and McLennan, 1985, Hans Wedepohl, 1995 and Rudnick and Gao, 2003; also see Mo et al., 2008); and arc rocks are highly enriched in Sr while bulk continental crust is relatively depleted in Sr (Niu and O'Hara, 2009). Besides, arc crust production and continental destruction (sediment recycling and subduction-zone erosion) have been demonstrated repeatedly to be mass balanced (von Huene and Scholl, 1991, Clift and Vannucchi, 2004, Clift et al., 2009, Niu and O'Hara, 2009 and Scholl and von Huene, 2009), implying that there is no net crustal growth associated with active seafloor subduction and arc magmatism. It has been accepted that the bulk continental crust has grown progressively through episodic magmatism over Earth history (Reymer and Schubert, 1984 and Condie, 2000). This notion requires a tectonic setting where juvenile crust is produced and also preserved in order to maintain the net crustal growth (see Niu and O'Hara, 2009 and Niu et al., 2013).

A hypothesis that continental collision zones are primary sites of net continental crustal growth was recently proposed by Niu et al. (2007), Mo et al. (2008) and Niu and O'Hara (2009) based on

studies of the India-Asia syncollisional (~ 55 Ma) andesitic rocks from southern Tibet (Mo et al., 2007a and Mo et al., 2008) in order to resolve the major problems that the standard 'island arc' model faces (see the above, and reviewed by Niu et al., 2013). These rocks, in particular the syn-collisional andesites, show remarkable compositional similarity to the bulk continental crust (Rudnick and Gao, 2003), yet have strong mantle isotopic signatures (Mo et al., 2007a and Mo et al., 2008). Their petrogenesis is interpreted to represent net mantle-derived materials added to the continents via partial melting of last fragments of underthrusting Tethyan ocean crust under amphibolite-facies conditions in a syn-collisional setting (Niu and O'Hara, 2009). Nevertheless, whether this hypothesis is valid for older syncollisional granitoids on a global scale still needs testing (Niu et al., 2013). The tectonic framework of the Northern Tibetan Plateau is characterized by the assembly of several collisions zones. Each syncollisional batholith belt is in excess of 1000 km long. If our petrologic and geochemical study proves that all these batholiths are dominated by juvenile material at the time of accretion, then we will be able to develop the concept into a quantitative theory on the origin and evolution of the continental crust.

In detail, these syn-tectonic granitoids deserve a comprehensive study using modern technics also because (1) these granitoids are voluminously important and tectonically associated with the regional metamorphisms; (2) they have not been neither precisely dated nor geochemically investigated, therefore, their petrogenesis is not clear nor convinced; (3) understanding of petrogenesis of these granitoids are of particular importance to understand the mechanisms of the continental crust growth; (4) the relationship between the sub-tectonic units are complex and contentious. Understanding of these granitoids can place more constraints on the orogenic evolution.

We conducted two two-week field trips in 2009 and 2010, respectively. We sampled from three batholith belts: the East Kunlun batholiths in the southern which is ~250 Ma years old; the granitoids in the Qilian Block in the middle, and the North Qilian Orogenic Belt which is ~ 500 Ma years old further in the north. We focused on the I-type granitoids containing the mafic magmatic

enclaves (MMEs) as well as some representative S-type granitoids. This thesis reports results from major and trace element data, whole rock Sr-Nd-Hf-Pb isotopic data, zircon geochronology and *in situ* Hf isotopes of granitoids as well as, if any, the enclosed MMEs.

The Giant East Kunlun Batholiths extend east–west for up to 1500 km with a north–south width of 50–200 km. In the light of the lack of knowledge (Chapter 3), the geochemical nature of representative granitoids from these batholiths as well as their enclosed mafic magmatic enclaves (MMEs) in the eastern part of the East Kunlun Orogenic Belt (EKOB), were investigated. These samples were chosen for study as they contain abundant MMEs and for this reason, offer particular insights into evolution of the granitoid magma and the mechanism of crust growth in the EKOB. The multiple geochemical data enable us to evaluate the relationship between these MMEs and their hosts which is essential to understand their petrogenesis as a whole and to quantify the geochemical endmembers in the source in order to further constrain the crust growth processes.

Samples in the Qilian Block (QB), north to the EKOB, provide the opportunity to reveal the nature and history of this region. These samples were chosen because (1) the QB is a unique tectonic unit which is important to understand the debatable tectonic history of the entire Qilian Orogenic Belt; (2) the granitoids cover a large compositional range and were little investigated, which limited the understanding of the QB.

In addition to the samples from the EKOB and the QB, samples from the Kekeli Batholith in the northern part of the Qilian Orogenic Belt are also studied in this Ph.D. project. Kekeli batholith is characterized by the abundant mafic cumulates and considered as the fossil magma chamber. It offers a unique opportunity to look into the early stage geochemical evolution of the granitoid magma.

Chapter 2 briefly introduces the analytical techniques and methods used throughout this study. The methods are also indicated and summarized in each chapter where appropriate.

Chapter 3 focuses on the petrography, geochronology and whole rock geochemistry and isotopes of the EKOB granitoids as well as their MMEs. The *in situ* U-Pb age analyses of zircon separates yield constraints on the age and evolution of the EKOB. Through geochemical compositions of the hosts and MMEs, their congenetic relationship is characterized. Petrogenesis of the granitoids and crust growth in terms of the tectonic evolution of the EKOB is discussed in this chapter.

Chapter 4 focuses on the petrography, geochronology and whole rock geochemistry and isotopes of the Qilian Block granitoids. Through the *in situ* U-Pb age analyses of zircon separates, the nature of the Qilian Block basement is characterized and the emplacement age of these granitoids is evaluated. Petrogenesis of the granitoids, crust growth and tectonic evolution of the Qilian Orogenic Belt is discussed in this chapter.

Chapter 5 presents additional zircon *in situ* Hf isotopes for the samples discussed in Chapter 4. More similar samples are investigated in this chapter. Some interpretations in Chapter 4 are re-evaluated and a new tectonic model is proposed.

Chapter 6 focuses on the petrography, geochronology, whole rock geochemistry and isotopes and zircon *in situ* Hf isotopes of samples from Kekeli Batholith in the North Qilian Orogenic belt. The effect of different mineral crystallizing timings on the Hf isotopic system is investigated.

Chapter 7 summarises the conclusions from each of the previous chapters and future work in order to present a comprehensive, concise and critical account of the nature and evolution of the magmatisms in the old collisions zones on the Northern Tibetan Plateau.

1.2. Chapter contributions

1.2.1. Chapter 2

I wrote this chapter in its entirety in order to provide a concise descriptions of techniques used throughout this study.

1.2.2. Chapter 3

The contents of this chapter have been published in Chemical Geology:

Huang, H., *Niu, Y.L., Nowell, G., Zhao, Z.D., Yu, X.H., Zhu, D.C., Mo, X.X. and Ding, S. 2014. Geochemical constraints on the petrogenesis of granitoids in the East Kunlun Orogenic belt, northern Tibetan Plateau: Implications for continental crust growth through syn-collisional felsic magmatism, Chemical Geology, 370, 1 – 18.*

Hui Huang: I collected the samples and carried out all of the lab work including petrography, cutting and crushing samples, major elements, trace elements, zircon U-Pb dating and whole rock Sr-Nd-Hf-Pb isotopes. I wrote the manuscript then passed it on to the co-authors.

Yaoling Niu: Yaoling is my primary supervisor. He provided the funding to do the entire Ph.D. project. He planned and carried out the sampling program. As the second corresponding author, he provided significant help with the discussion of the results and constructive criticism throughout the preparation and publication of the paper.

Geoff Nowell: As my second supervisor, Geoff provided unwavering assistance and support during the whole-rock Sr-Nd-Hf-Pb isotope analysis in the lab and on the instrument. He assisted data processing, assessed data quality and discussed the initial data interpretations.

Zhidan Zhao: Zhidan was one of major members who carried out the field work. He arranged the zircon U-Pb dating analysis in China University of Geosciences, Wuhan in 2009 and 2010.

Xuhui Yu: Xuehui was one of the major members who carried out the field work.

Dicheng Zhu: Dicheng was one of the major members who carried out the field work.

Xuanxue Mo: Xuanxue was one of the major members who carried out the field work.

Shuo Ding: Shuo provided invaluable assistance throughout the field and lab work except the whole-rock isotope analysis.

1.2.3. Chapter 4

The work presented here has been submitted to *Gondwana research* and is currently in press.

Hui Huang: I did the sampling and carried out all of the lab work including petrography, cutting and crushing samples, major elements, trace elements, zircon U-Pb dating and whole rock Sr-Nd-Hf-Pb isotopes. The interpretations and discussion were benefitted from the discussions with Yaoling. I wrote the manuscript then passed it on to the co-authors.

Yaoling Niu: Yaoling provided the funding to carry out the project in the field and in the lab. He was the one of the major members in the field. He provided constructive feedback throughout the preparation and publication of the paper.

Geoff Nowell: Geoff was available for technical assistance with the instrument, assessing the data quality and data processing.

Zhidan Zhao: Zhidan was one of major members who carried out the field work. He arranged the zircon U-Pb dating analysis in China University of Geosciences, Wuhan in 2009 and 2010.

Xuhui Yu: Xuehui was one of the major members who carried out the field work.

Xuanxue Mo: Xuanxue was one of the major members who carried out the field work.

1.2.4. Chapter 5

The work detailed here will be submitted as a paper to *lithos*.

Hui Huang: I did the sampling and carried out all of the lab work including petrography, cutting and crushing samples, major elements, trace elements, zircon U-Pb dating, zircon *in situ* Hf isotope and whole rock Sr-Nd-Hf-Pb isotopes. I arranged the zircon *in situ* Hf isotope analysis in Northwest city, Xi'an in 2009 and in Chinese Academy of Sciences, Beijing in 2011. The interpretations and discussion were benefitted from the discussions with Yaoling.

Yaoling Niu: Yaoling provided the funding to carry out the project in the field and in the lab. He was the one of the major members in the field. He provided constructive criticism on the original manuscript.

1.2.5. Chapter 6

The work detailed here will be submitted as a paper to *Earth and Planetary Science Letters.*

Hui Huang: I did the sampling and carried out all of the lab work including petrography, cutting and crushing samples, major elements, trace elements, zircon U-Pb dating, zircon *in situ* Hf isotope and whole rock Sr-Nd-Hf-Pb isotopes. I arranged the zircon *in situ* Hf in Chinese Academy of Sciences, Beijing in 2011. The data was modelled and interpreted by me.

Yaoling Niu: Yaoling provided the funding to carry out the project in the field and in the lab. He was the one of the major members in the field. He provided constructive criticisms on the original manuscript.

Geoff Nowell: Geoff was available for technical assistance with the instrument and assessing the data quality. He discussed the initial data interpretations.

Chapter 2: Methodology

2.1. General sample preparation

Samples were collected from the Northern Tibetan Plateau in 2009 and 2010. All the analyzed samples were fresh rock chips by chipping off the weathered surfaces and saw/pen marks. Each sample was split into 2 or 3 parts. One part was for 30 μm and 60 μm thick thin sections. One part was crushed into rock powders (particle size < 50 μm) using agate ball mills. Six samples can be done in one run. Before crushing, all the chips were leached in 5% HCl solution, washed ultrasonically in milli-Q water and dried in a clean environment. The agate ball mills were thoroughly cleaned in water, ethanol and compressed air. The remaining parts (for some dated samples) were crushed to extract zircons. Thin sections are for petrographic observations. Zircon extractions are for zircon U-Pb dating and *in situ* Hf analysis. Whole rock powders are for major and trace element concentrations and Sr-Nd-Pb-Hf isotopic compositions.

2.2. Major element geochemistry-XRF

Major element analysis was done using XRF（PANalytical Axios Advanced PW4400) on fused glass disks in Tianjin Institute of Geology and Mineral Resources, China following the method of Li et al. (2011). The precision on standards (GSR-1, GSR-3, GSR-8, GSR-9) was better than 3% and mostly better than 0.5%. Standard data are given in Appendix A.

2.2.1. The loss on ignition (LOI)

The volatile phases within the sample powders, e.g. chlorine, CO_2, fluorine, H_2O can be lost during the fusion process and lead to the weight change, i.e. LOI, which cannot be detected by XRF analysis. LOI values can also be negative due to the weight gain by iron oxidation, i.e. FeO to Fe_2O_3.

~ 0.5g of rock powder (M1) was weighed out and dried at 120 °C in a Gallenkamp oven overnight to remove the non-structural moisture. The weight of clean Pt-At crucibles was measured as M2, then ~ 0.5g of sample (M1) was weighed into the crucible. After that, crucibles were placed in the

furnace at 1000°C for 2 hours and weighed as M3 after cooling. The LOI values were calculated as 100×(M1+M2-M3)/M1.

2.2.2. Glass disc preparation

~ 5 g mixed flux with lithium tetraborate ($Li_2B_4O_7$): lithium metaborate ($LiBO_2$) ratio of 67:33 was added to each sample in Pt-Au crucibles to aid dissolution. 1 ml 300 g/L ammonium nitrate (NH_4NO_3) was used as oxidant. Two drops of lithium bromide (LiBr) was used as mold-release agent. They were pre-oxidized at 600 °C for 200 s and then fused at 1000 °C for 9 mins. The melt in the crucible was cooled and a disc-shaped sample piece was formed and ready for analysis.

2.3. Trace elements-ICP-MS

Trace element analysis was done using ICP-MS (Thermo Scientific X seriesII) after acid digestion/dissolution in Teflon bombs in Tianjin Institute of Geology and Mineral Resources, China. Standard data are given in Appendix A.

Fifty mg of rock powder was digested with mixture of 1 ml of HF and 0.5 ml of HNO_3 in a Teflon beaker within a screw top stainless steel bomb at 190°C for 24 hours. Teflon beakers were taken out after cooling and left on a hot plate at 200°C to evaporate until the dryness. Then 0.5 ml HNO_3 was added into the beaker and evaporated to dryness. Another 0.5 ml HNO_3 was added and evaporated to dryness. The beaker was put back inside the steel jackets (bomb) after another 5 ml HNO_3 was added. The bomb was tightly sealed and kept on hot plate at 130°C for 3 hours. Then, the sample was transferred into clean beaker and the final dilution was made to 50 ml using 18M Mili-Q water. The instrument is Thermo Scientific X series^{II} ICP-MS. The reproducibility of elemental concentrations assessed by triple runs of the same solution during an analysis period.

2.4. Zircon U-Pb geochronology

About 100-150 zircon grains for each of the studied samples were mounted in an epoxy resin disc and then grinded/polished to expose the zircon interiors for imaging and analysis. All the polished

zircon grains were photographed under transmitted- and reflected-light, and further examined using cathodoluminescence (CL) images prior to the U-Pb analyses. Laser ablation ICP-MS zircon U-Pb analysis was carried on an Agilent 7500 ICP-MS instrument equipped with a GeoLas 2005 at China University of Geosciences, Wuhan. Detailed operating conditions for the laser ablation system and ICP-MS instrument and data reduction are the same as described by Liu et al. (2008). Zircon 91500 was used as the external standard and ran twice every 5 samples. Standard silicate glass NIST610 was used to optimize the instrument. Beam diameter was 30 μm. Common Pb was corrected by ComPbCorr#3_17 (Andersen, 2002). Age calculations and Concordia plots were made using isoplot (Ludwig, 2003).

2.5. Zircon *in situ* Hf isotope-LA-ICP-MS

Zircon *in situ* Hf isotopes were conducted for samples from the Qilian Block and Kekeli batholiths. Some zircons have obvious cores and some of them show complex internal growth domains, it is important to have the ages and Hf isotopes analysed within the same and adjacent spots. We selected zircons with <10% discordancy between $^{207}Pb/^{235}U$ and $^{206}Pb/^{238}U$, the ages and Hf isotopic compositions are thought to record largely or entirely magmatic events, with the zircons with >10% discordancy (not analyzed for Hf isotopes) reflecting either inherited components, Pb loss, or metamorphic overgrowth.

Samples collected in 2009 with "QL09" initials in their names were analysed using a Nu Plasma HR MC-ICP-MS equipped with a GeoLas 2005 laser-ablation system, with a spot size of 44 μm and a repetition rate of 10 Hz, at the State Key Laboratory of Continental Dynamics, Northwest University in Xi'an, China. The detailed analytical technique was described by Yuan et al. (2004). High-purity argon (99.9995%) and high-purity helium (99.9995%) were used as the carrier gas to enhance the efficiency of the aerosol transport. Raw count rates for ^{172}Yb, ^{173}Yb, ^{175}Lu, ^{176}(Hf+Yb+Lu), ^{177}Hf, ^{178}Hf, ^{179}Hf, ^{180}Hf and ^{182}W were collected and isobaric interference corrections was made for ^{176}Hf. $^{179}Hf/^{177}Hf$ ratio was applied to calculate the mass fractionation of Hf (βHf), the

^{175}Lu signal was used to calculate the interference of ^{176}Lu on ^{176}Hf, and ^{173}Yb–^{172}Yb–^{171}Yb was applied to calculate both βYb and the interference of ^{176}Yb on ^{176}Hf. A ^{176}Yb/^{172}Yb of 0.5887 and mean βYb on the same spot were applied for the interference correction of ^{176}Yb on ^{176} Hf. ^{176}Hf/^{177}Hf and ^{176}Lu/^{177}Hf ratios of the standard zircon (91500) were 0.282294±15 (2σ, n =38 and 0.00031(2σ, n =30),. 91500, MON-1 and GJ-1 standard zircons were run during of analyses and gave ^{176}Hf/^{177}Hf ratios of 0.282295 ±0.000007) and 282013 ±0.000009 respectively. Interference of ^{176}Lu on^{177}Hf was corrected by measuring the intensity of an interference-free ^{175}Lu isotope and using a recommended ^{176}Lu/^{175}Lu ratio of 0.02669 to results of the samples.

Samples collected in 2010 with "QL10" initials in their names were analyzed using the Neptune multicollector (MC) ICP-MS, equipped with a 193 nm laser, at the Institute of Geology and Geophysics, Chinese Academy of Sciences in Beijing, China. The analytical technique was described by Wu et al., (2006).

2.6. Whole rock Sr-Nd-Pb-Hf isotopes

Whole rock Sr-Nd-Pb-Hf isotope ratios were determined using a PIMMS (Plasma Ionisation Multicollector Mass Spectrometry) ThermoElectron Neptune instrument at the Arthur Holmes Isotope Geology Laboratory (AHIGL), Durham University. Water used throughout the procedure was Milli-Q water (~18.3 MΩ m^{-1}) for diluting acids and as a reagent. All dissolutions were undertaken in laminar flow fume hoods and in Teflon beakers. The standard data, blanks and repeated Nd isotope analyses throughout this study are given in Appendices B-E.

2.6.1. Dissolution procedure

~100 mg of sample is required for the whole rock Sr-Nd-Pb-Hf analyses. The USGS reference standards were BHVO-1 and BIR-1. Each batch contains 16-18 samples, 1~2 standards and 1~2 chemical blanks.

1. Weigh out ~ 0.1 g of sample and BHVO-1 and ~ 0.5 g of BIR-1 into a clean 7 ml Teflon beakers.

2. Add 3 ml TD 29N HF and 1 ml TD 16N HNO3. Place on hotplate in a hotplate overnight at 100 °C.

3. Dry down solution to a paste at 100 °C.

4. Add 1 ml TD 16N HNO_3 to re-dissolve. Leave on hotplate overnight at 100 °C.

5. Dry down solution to a paste at 100 °C.

6. Add 1 ml TD 16N HNO_3 and dry down completely.

7. Add 0.5ml TD 3N HNO_3 and leave on hotplate at 40 °C to dissolve the samples.

8. Transfer solution to 1.5 ml microcentrifuge tubes pre-rinsed with 3N TD HNO_3. Centrifuge at 13000 rpm for 15 minutes. Any insoluble precipitates will form a solid mass at the base of the tube.

2.6.2. Sr-Spec column chemistry for collecting Nd-Hf, Sr and Pb fractions---Sr and Pb is ready in this step

Column (1000 µl pipette tips**) set up:**

1. Rinse with 1 CV (column volume) of MQ H_2O.

2. Rinse with 1 CV of TD 6N HCl.

3. Rinse with 1 CV (column volume) of MQ H_2O.

4. Load ~60 µl Sr-spec resin as a slurry in MQ H_2O. Ensure column is free of air bubbles in and around the frit.

5. Elute 1 CV TD 6N HCl.

6. Elute 2 CV MQ H_2O.

7. Precondition resin with 200 µl TD 3N HNO_3.

Elution Procedure:

1. sample loading: 100~ 500 µl TD 3N HNO_3 from 500 µl microcentrifuge tube using 2 x200 µl pipette – **do not** disturb the solid precipitates, collect in clean 7 ml Teflon beaker.

2. Hf-Nd collection: Add 2x 250 µl TD 3N HNO_3, collected to Nd-Hf fraction beaker.

3. Sr collection: Add 2x 200 µl MQ H2O and collect Sr fraction to the Sr fraction micro-tubes (rinsed with 6N HCl).

4. waste elution: Elute 2x100 µl TD 2.5N HCl, not collecte.

5. Elute 2×50 µl TD 8N HCl, collected to Pb fraction in micro-tubes.

Finish: Dispose of column by wrapping it carefully in cling film so that the dry resin will not become airborne.

Dry Sr and Pb fractions down on hotplate at 80 °C.

2.6.3. Column chemistry for collections of Hf and Nd

2.6.3.1. Sample preparation

Dry collected Nd-Hf fractions on the hotplate at 100°C.

Dissolve in 1 ml 1N TD HCl on hotplate at 100°C.

2.6.3.2. Nd and Hf cation column procedure—Nd fraction is ready in this step

Note: unless stated, collect to waste beakers.

Pre-procedure cleaning

1. Wash Nd-Hf cation column tips with 6N HCl.

2. Rinse with 5 mls TD 29N HF.

3. Rinse with 10 mls MQ H_2O.

4. Rinse with 10 mls 6N TD HCl.

5. Rinse with 10 mls MQ H_2O.

6. preconditioning with 10 mls TD 1N HF – 1N HCl.

Hf and Nd elution procedure

1. sample loading: 1 ml TD 1N HCl, collect

2. Hf collection: Elute 3 mls TD 1N HF– 1N HCl

3. waste elution: Elute 14 mls TD 2.5N HCl

4. Ba elution: 10mls TD 2N HNO_3.

5. Nd collection: Elute 12mls TD 6N HCl.

Nd-Hf column cleaning

1. Wash column tips with 5mls TD 29N HF.

2. Rinse with 10 mls MQ H_2O

3. Rinse with 10 mls 6N TD HCl.

2.6.3.3. Hf column chemistry—Hf fraction is ready in this step

Hf elution procedure

Sample Loading: 1ml 0.52N H_2SO_4-5%H_2O_2, not collected

Ti elution: 5ml 0.52N H_2SO_4-5%H_2O_2, not collected

Ti elution: 5ml 0.52N H_2SO_4-5%H_2O_2, not collected, elute until the yellow color is gone.

Hf collection: 4 ml TD 1N HF-2N HCl, collected

Hf column cleaning

1, 5ml TD 29N HF

2, 5ml MQ H_2O

3, 4ml 12N H_2SO_4

4, 5ml MQ H_2O

Precondition the column with 5ml H_2SO_4-5%H_2O for next batch.

2.6.4. Beak cleaning

1. Remove any labels with ethanol.

2. Rinse beakers and lids with MQ H_2O.

3. Wipe inside of beaker with micropure wipe to dislodge any remnant material.

4. Fill beaker to a depth of 1 cm with ANALAR HCl. Rotate beaker to dispatch HCl around the beaker and discard.

5. Fill to a depth of 0.5 cm with 29N HF (used HF stock from step 14) and leave on hotplate at 90 °C for 24 hours.

6. Remove from hotplate and leave to cool for 30 minutes -1 hour.

7. Remove HF and rinse beaker with MQ H_2O.

8. Immerse beakers in 900 ml of 90% MQ H_2O – 10% 16N HNO_3 for 24 hours at 100 °C.

9. Remove beakers from acid and rinse twice with MQ H_2O.

10. Immerse beakers in 1 litre of MQ H_2O for 24 hours at 60-100 °C.

11. Remove beakers from MQ H_2O and rinse thoroughly with MQ H_2O.

12. Fill beakers to a depth of 0.5 cm, cap, and place on hotplate overnight at 100 °C.

13. Remove from hotplate and leave to cool for 30 minutes -1 hour.

14. Discard HF and rinse with MQ H_2O.

15. Leave beakers and lids to dry upside down on micropure wipe.

16. Beakers cleaned and ready for use.

Chapter 3: Granitoids and their enclaves from the East Kunlun Orogenic Belt

3.1. Introduction

The Greater Tibetan Plateau is an ideal test ground as it records several continental collision events since the Early Paleozoic (Dewey et al., 1988, Harris et al., 1988a and Yin and Zhang, 1997), as indicated by a number of suture zones with associated syn-collisional granitoid batholiths increasingly younger from the northeast to southwest (Fig. 1A, Harris et al., 1988a). The East Kunlun Orogenic belt (EKOB) in the northern part of the Plateau, which includes abundant syn-collisional granitoids, is one of the largest continental collision zones. It is much older than the India-Asia collision (~ 250 Ma vs. ~ 55 Ma). The A'nyemaqen suture zone in the southern EKOB records the closure of the Paleo-Tethyan Ocean and a continental collision event (Yang et al., 1996 and Yang et al., 2009). The abundant late Permian to early Triassic granitoids along the EKOB have not been properly studied but only mentioned in regard to subduction/collision related (Harris et al., 1988a, Jiang et al., 1992 and Yin and Harrison, 2000) hybrids between mantle-derived melts and crustal materials (Luo et al., 2002, Deng et al., 2004, Chen et al., 2005 and Mo et al., 2007b). This interpretation is based on the observations that most EKOB intrusions are I-type granitoids containing mafic magmatic enclaves (MMEs, see definition by Barbarin, 2005) with the latter being considered as representing mantle-derived melts. The same age and overlapping radiogenic isotope compositions between the host granitoids and MMEs are considered as evidence for mixing and "homogenizing" processes (Liu et al., 2004a and Mo et al., 2007b) although it is physically not straightforward how the invoked mixing and "homogenizing" processes only 'homogenized' isotopes without affecting major element compositions.

Here we report major elements, trace elements and bulk-rock Sr-Nd-Pb-Hf isotopes and zircon U-Pb age data on granitoids and MMEs from the EKOB to constrain the petrogenesis of these rocks in the context of understanding the evolution of the EKOB, which also helps understand the evolution of the Paleo-Tethyan system and mechanisms of crust growth in response to continental collision.

3.2. Geological setting

3.2.1. Regional and local geology

The EKOB records a complex history of seafloor spreading, subduction and continental collision since the early Paleozoic (Jiang et al., 1992, Yang et al., 1996 and Yin and Harrison, 2000). It lies on the northern Tibetan Plateau with the Songpan-Ganzi Basin to the south and Qaidam Basin to the north (Fig. 1A), and can be subdivided into three tectonic zones according to the major faults (northern, middle and southern zones, see Fig. 1B, Jiang et al., 1992 and Yang et al., 1996).

3.2.1.1. Stratigraphy and metamorphic rocks in the EKOB

The basement is dominated by Precambrian granitic gneisses with minor Proterozoic granitoids and migmatites. It crops out in all the three zones overlain by early Paleozoic sedimentary rocks (Harris et al., 1988a, Jiang et al., 1992 and Yang et al., 1996) and is considered to have been emplaced between 1.8 Ga and 0.9 Ga (Mo et al., 2007b and references therein). The granitic gneiss represented by the Shaliuhe granitic gneiss in the north EKOB has a peak magmatic age of ~ 920 Ma (Chen et al., 2007c) and a metamorphic age of ~ 400–500 Ma (Zhang et al., 2003b and Chen et al., 2007c). Whole rock Sr–Nd–Pb and zircon *in situ* Hf isotope data indicate that its protolith is upper crustal sedimentary rocks of middle Proterozoic age (Harris et al., 1988a, Chen et al., 2007b and Chen et al., 2007c). The late Permian molasses and the angular unconformity between the upper-Permian to lower-Triassic marine strata and lower-Permian terrestrial strata have been recognized in the Paleozoic–Mesozoic sedimentary cover (Jiang et al., 1992, Zhang et al., 2004 and Li et al., 2008), indicating a continental uplift event during that time.

Some ophiolites (Yang et al., 1995 and Yang et al., 1996) are exposed along the central Kunlun fault (CKLF) and Kunlun Fault (Fig. 3.1C), especially in the southern zone, named the A'nyemaqen ophiolite belt. The most precise zircon U–Pb age on these ophiolites within the southern zone is reported for the Dur'ngoi ophiolitic basalt, which is ~ 308 Ma (Yang et al., 2009).

3.2.1.2. East Kunlun Batholiths (EK batholiths)

The EKOB contains one of the two largest granitic batholiths on the Greater Tibetan–Plateau (the other being the Gangdese belt in Southern Tibet). The 'Kunlun Batholiths' (Jiang et al., 1992 and Mo et al., 2007b) cover 48,400 km^2, cropping out mostly in the EKOB middle zone (Fig. 3.1C). The batholiths are mainly monzonite and granodiorite in composition with ages ranging from the Proterozoic to the late Mesozoic (Jiang et al., 1992). The Proterozoic granitoids are part of the Precambrian basement. Early Paleozoic granitoids (400–500 Ma) have been interpreted as resulting from subduction–collision events comparable to that which produced magmatism in the Qilian orogenic belt to the north (Mo et al., 2007b). The granitoids of Late Permian–Early Triassic (P–T) age are dominant in the EKOB with an area of 23,000 km^2 (Liu et al., 2004a), almost half of the entire batholiths (Mo et al., 2007b). Previous studies indicate that the P–T granitoids are calc-alkaline and formed during the major subduction-related orogenic period (240– 260 Ma) (Harris et al., 1988b, Yin and Harrison, 2000 and Mo et al., 2007b). Minor mid-late Mesozoic granitoids are also present which might be related to the post-collisional magmatism (Jiang et al., 1992 and Mo et al., 2007b). The crystallization ages of P–T granitoids have been determined reliably, yet the origin and petrogenesis of the giant batholiths remains poorly understood. For example, what tectonic setting were they emplaced in during a relatively short time period?

We collected 30 representative samples from 14 locations (GPS data are given in Table 3.1) around south Dulan and southwest Qinghai Lake (Fig. 3.1C). The granitoids contain abundant MMEs (Fig. 3.2A), and thus are ideal to test our hypothesis on the origin of these MMEs in the context of the granitoid petrogenesis. Duplicate samples from some host rocks and MMEs were collected on a meter/centimeter scale in order to look into the potential heterogeneity.

3.2.2. Petrography

The granitoids are mainly granodioritic in nature with minor granitic and dioritic compositions. They are medium to coarse-grained with equigranular textures. The mineralogy is relatively simple, and is dominated by quartz (Qz, 45–35%), plagioclase (Pl, 35–45%), K-feldspar (Kfs, 5–10%), biotite (Bt, 5%) and minor amphibole (Amp, 2–5%) (Fig. 3.2C). Accessory minerals include apatite, zircon, and Fe–Ti oxides. The fine grained MMEs are mafic diorite to diorite in composition (Figs. 3.2D and 3.3) with oval shapes and varying sizes (Fig. 3.2A, B). An important observation is that the MMEs have the same mineralogy as the granitoid hosts with higher modes of the mafic minerals such as Amp (30–45%) and Bt (5–10%) (Fig. 3.2D). No crystal resorption textures and reactive overgrowths have been observed (Fig. 3.2D).

3.3. Analytical results

30 samples (17 granitoid hosts and 13 MMEs including 10 host-MME pairs; Table 1) were analysed for major and trace elements. Thirteen samples (including 6 enclaves) were extracted for zircons. Seventeen samples (including 7 enclaves) were analysed for whole rock Sr-Nd-Pb-Hf isotopic compositions.

3.3.1. Major and trace elements

Host granitoids are more silicious than the contained MMEs (Fig. 3.3). All of them are calc-alkaline (Fig. 3.3) and metaluminous (A/CNK < 1.1, Table 3.2). Three MME samples chemically fall into the gabbro field (Fig. 3.3), but they are Amp-rich mafic-diorites with no pyroxene present.

Host rocks and MMEs define good linear trends for most elements on Harker diagrams (Fig. 3.4). TiO_2, Al_2O_3, FeO, MnO, MgO, CaO, Eu and Yb exhibit well defined negative trends, which likely reflect the fractionation of Amp, Bt and Pl.

Both MMEs and granitoid hosts have an enriched LREE and flat HREE profile lacking a garnet signature (no depletion of HREEs) (Fig. 3.5A, B). The average compositions of the granitoid hosts

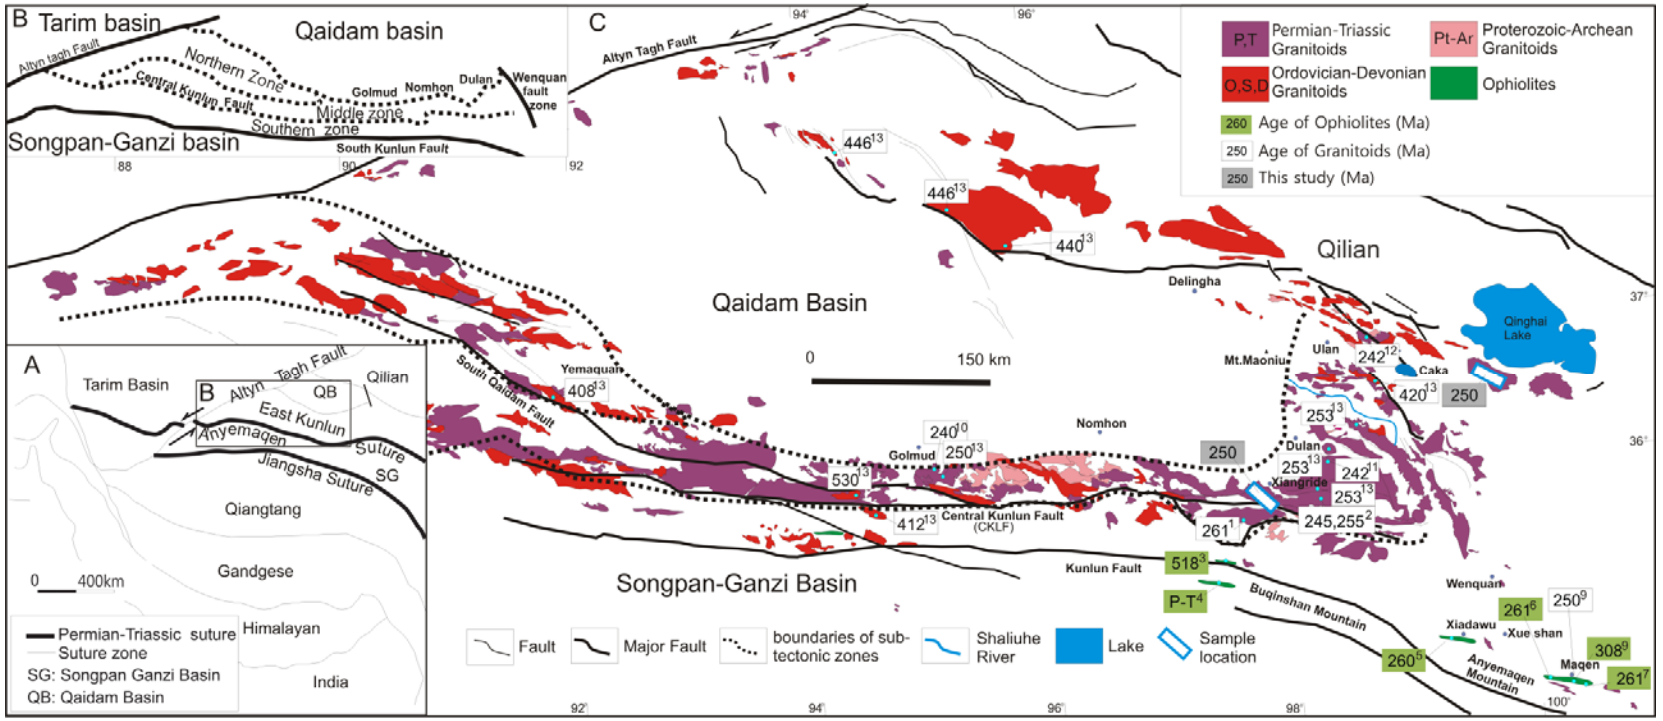

Fig. 3.1. A, Schematic map showing major tectonic units of West China. B, Schematic map showing three sub-tectonic zones of the East Kun Orogenic Belt (EKOB; after Jiang et al., 1992). C, Simplified geological map of the East Kunlun Orogenic Belt and the adjacent Qaidam Basin region showing the distribution of granitoids and ophiolites (after Pan et al., 2004). 1: Naomuhun Pluton, 261 Ma (Xiong et al., 2011). 2: Yuegelu Pluton, 243 ~ 256 Ma (Liu et al., 2004b); Halagetu Pluton: 255 Ma (Sun et al., 2009). 3-4 data is from Yang et al., (1996). 3: Qingshuiquan Ophiolite, 518 Ma (Zircon U-Pb). 4: Buqingshan Ophiolite: poorly dated, maybe late Permian to early Triassic. 5: Xiadawu Ophiolite, 260 Ma (Rb-Sr), (Jiang et al., 1992). 6-8 data is from Yang et al., (1996). 6: Majixueshan Ophiolite, Volcanic rocks: 260 Ma (Rb-Sr). 7: Maqen Ophiolite: poorly dated, maybe late Permian to early Triassic. 8: Wanbaogou Ophiolite: poorly dated, maybe late Permian to early Triassic. 9: Dur'ngoi Ophiolite, 308 Ma (Zircon U-Pb) (Yang et al., 2009a). 10, Deqia granitic complex, 250 Ma (Zircon U-Pb) (Yang et al., 2005). 11: Golmud East, Granodiorite, 240±6 Ma (Zircon U-Pb) (Harris et al., 1988a). 12, Xiangride Pluton, 242 Ma, compilation after Chen et al., (2007b). 12, Chahannuo Pluton, 242 Ma, compilation after Chen et al., (2007b). 13, data from compilation of Chen et al., (2011).

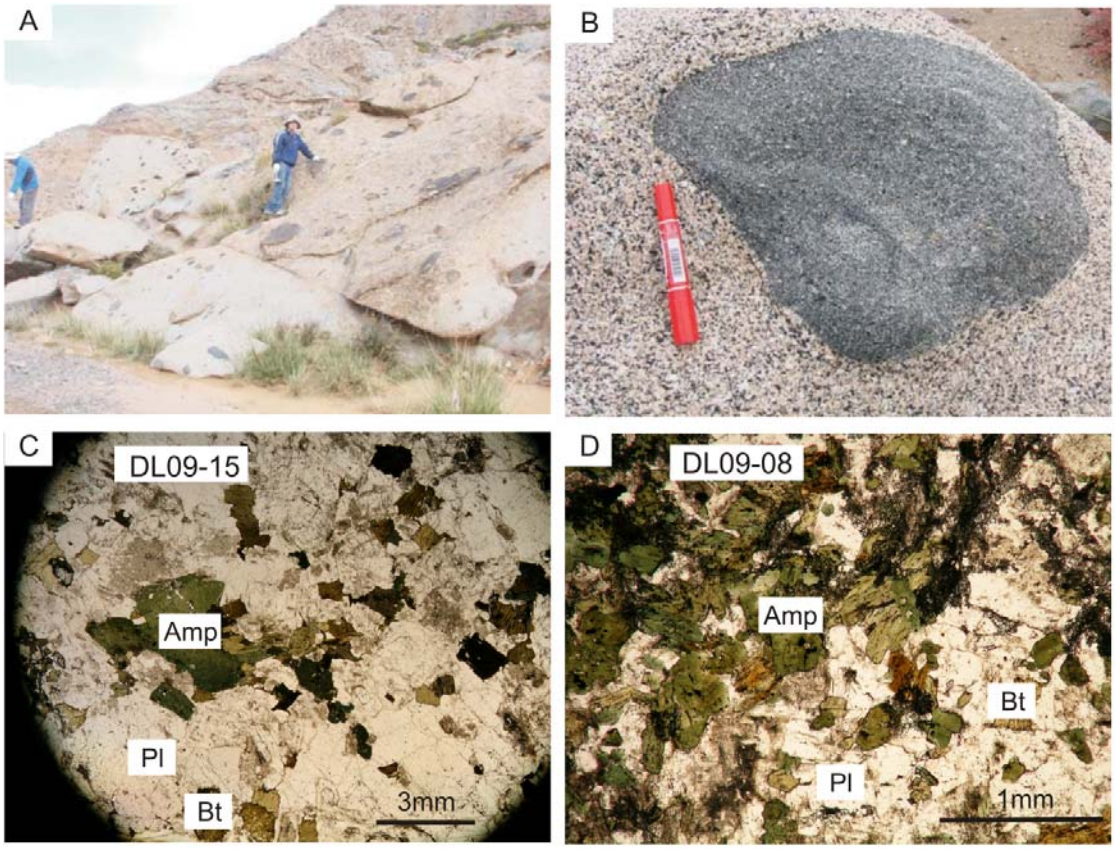

Fig. 3.2. Field photos in the Dulan area (A-B) and photomicrographs under plane polarized light of the representative granitoid host rock (C) and enclaves (MME) (D).

display apparent similarity to the bulk continental crust (BCC) composition in terms of all the analyzed elements and key elemental ratios (Fig. 3.5C, D) except for the lower Cr, Co, Ni, Sc and Mg in granitoids from the EKOB (Fig. 3.5C). The lower concentrations of Ni, Cr and Mg relative to the calculated modal BCC composition are typical for normal andesites (vs. high Mg andesites) and fully discussed by Niu and co-authors (Mo et al., 2008, Niu and O'Hara, 2009 and Niu et al., 2013). The slightly higher Th/U in the hosts compared to BCC (Fig. 3.5D) may be inherited from the Paleo-Tethyan MORB (see below) as it has a distinctly higher $^{208}Pb/^{204}Pb$ at a given $^{206}Pb/^{204}Pb$ compared to other MORB (Xu et al., 2002). MMEs display higher abundances of HREEs (Fig. 3.5A), reflecting their greater

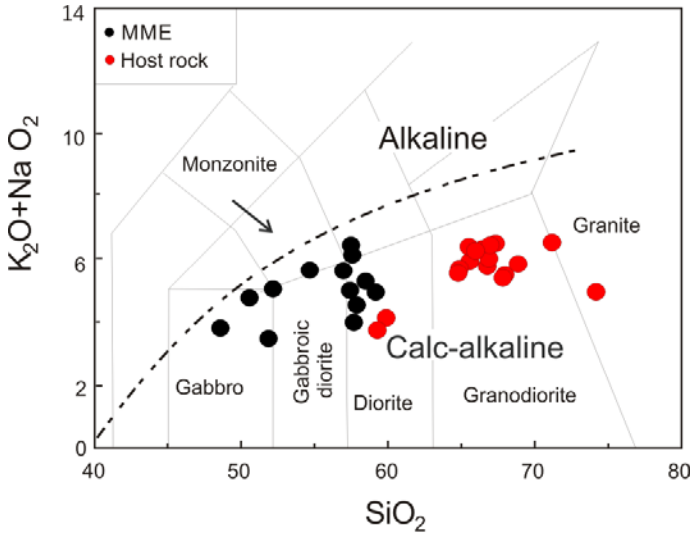

Fig. 3.3. Total alkalis (Na_2O+K_2O) versus SiO_2 (TAS) diagram showing the compositional variation of EKOB samples. The MMEs are generally less felsic than the hosts. Three samples in the gabbro field are actually mafic-diorite without pyroxene. All the samples are calc-alkaline. The dashed line represents the division between Alkaline and Cal-alkaline fields (Irvine and Baragar, 1971).

proportions of mafic minerals (e.g., Amp and Bt). The Nb/Ta ratios are all sub-chondritic (chondritic value of 17.5, Sun and McDonough, 1989), 11.84 for host rocks and 13.07 for enclaves. The slightly higher Nb/Ta ratios for enclaves are consistent with higher modal Amp which has super-chondritic Nb/Ta ratios (Foley et al., 2000) as elaborated by Niu and O'Hara (2009). The Sr/Sr* ($Sr/Sr^* = 2 \times Sr_N / [Pr_N + Nd_N]$) and Eu/Eu* ($Eu/Eu^* = 2 \times Eu_{PM} / [Sm_{PM} + Gd_{PM}]$) for host rocks are 0.78 and 0.84, respectively. The MMEs have slightly lower Sr/Sr* (0.48) and Eu/Eu* (0.67) due to a lesser amount of plagioclase. It is important to note that the sub-chondritic Nb/Ta ratios, Nb–Ta–Ti depletion and slight Sr–Eu depletions of these samples are identical to those of the BCC (Fig. 3.5D) (also see Niu and O'Hara, 2009).

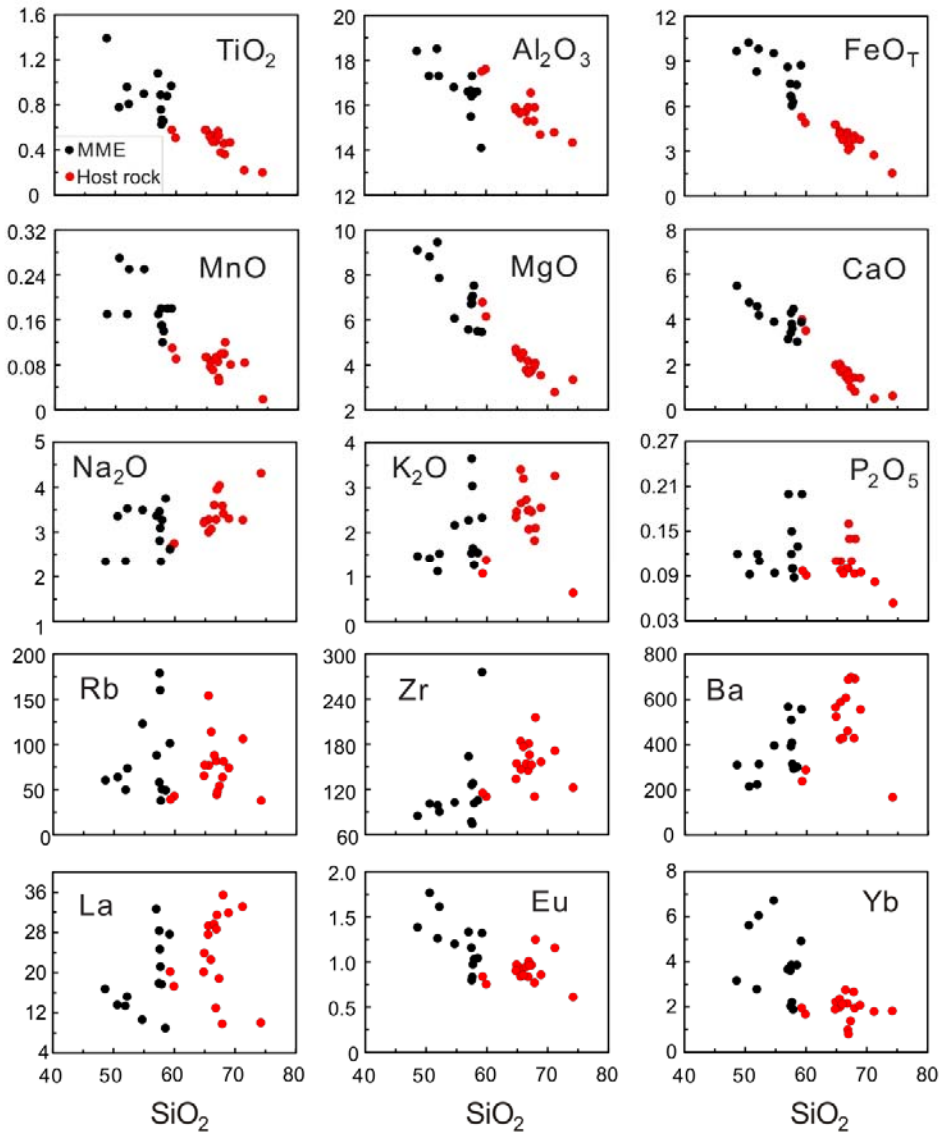

Fig. 3.4. SiO_2 variation diagrams of representative elements of the EKOB samples, showing fractional crystallization dominated trends.

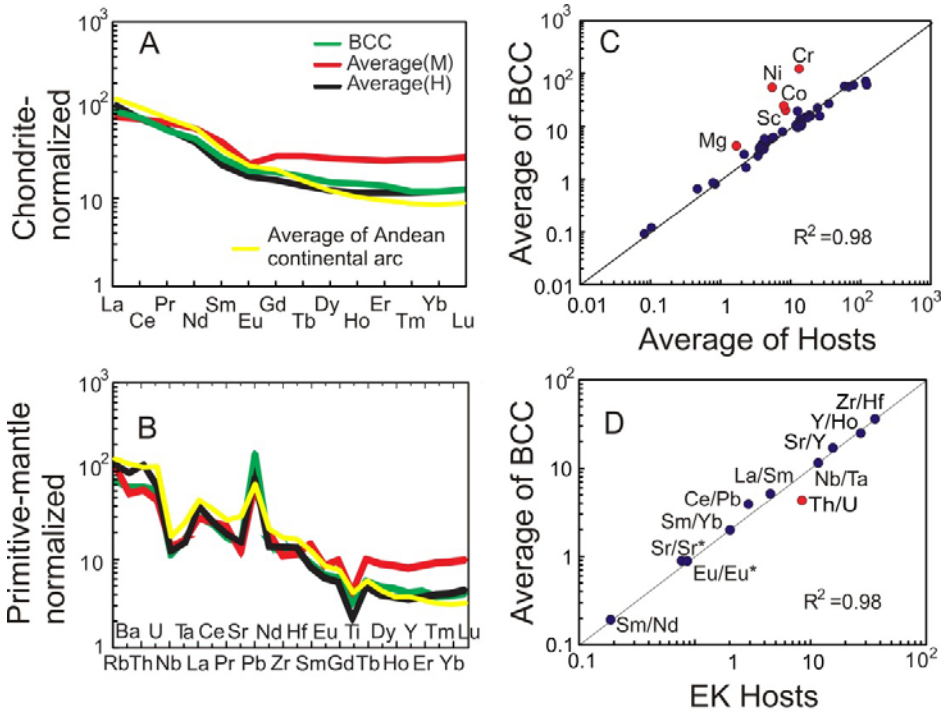

Fig. 3.5. A, Chondrite-normalized (Sun and McDonough, 1989) rare earth elements (REE) patterns for average compositions of the EKOB granitoid hosts (H) and mafic magmatic enclaves (MME, M). Bulk continental crust (BCC; Rudnick and Gao, 2003) and average of Andean continental arc (yellow line, data from http://georoc.mpch-mainz.gwdg.de/georoc/, basaltic andesitic to andesitic compositions) are also shown for comparison. Andean continental arc is remarkably similar to the BCC and our host rocks too. B, Primitive mantle-normalized (Sun and McDonough, 1989) multi-element patterns as in panel A. C, One-to-one plot to show the similarity between the granitoid hosts of the EKOB samples and the BCC in terms of the analyzed major and trace elements. D, Comparision between the granitoid hosts and the BCC in terms of key elemental ratios.

3.3.2. Zircon U-Pb Geochronology

Zircons from host rocks are on average ~ 100–200 μm long, colorless and euhedral with good prisms and pyramid faces, and have small elongation ratio of 1:1 to 3:1. They are either uniform or have oscillatory zoning (Fig. 3.6). Some of them have inherited cores with magmatic overgrowth rims. The Th/U ratios are mostly within the range of 0.4–0.6. A few old inherited zircons with Th/U < 0.1 (Table 3.3) have discordant ages (Fig. 3.7). Zircons from MMEs are brown in color, show cracks under transmitted and reflected light, and are characterized by high length/width ratios

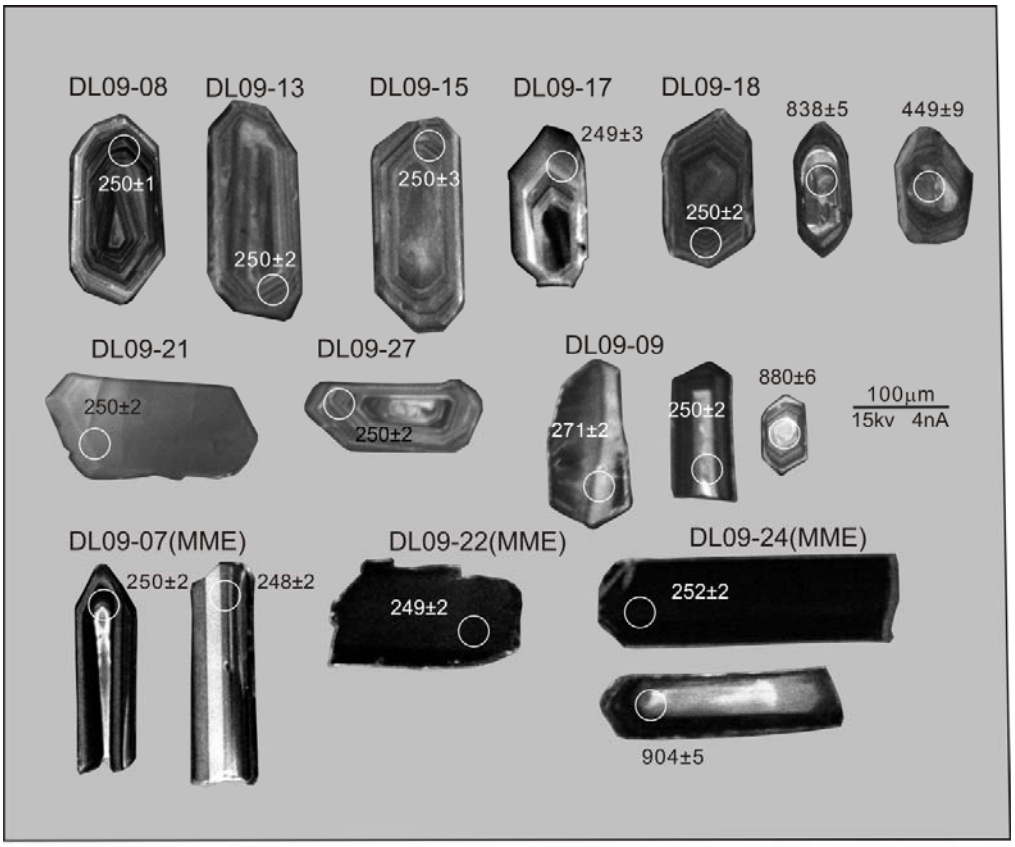

Fig. 3.6. Cathodoluminescence (CL) images of zircons from representative samples. White circles are the analyzed spots. The values with error are ages in Ma.

and straight rhythmic stripes (Fig. 3.6). Most zircons yield concordant or slightly discordant U–Pb ages. Zircon U–Pb ages of 7 granitoid hosts indicate that the intrusions were emplaced principally in the late Permian and early Triassic ~ 250 Ma (Fig. 3.7). All the 6 MMEs have an identical age to host rocks within error, i.e. ~ 250 Ma (Fig. 3.7). Inherited zircon cores which occur in both MMEs and host rocks, plot along or close to the Concordia, yielding age populations around 400–500 Ma and 800–1000 Ma (Fig. 3.6 and Fig. 3.7). These are identical respectively to the metamorphic and magmatic ages recorded in the Shaliuhe gneiss in the region (Zhang et al., 2003a, Meng et al., 2005b and Chen et al., 2007c).

3.3.3. Whole rock Sr-Nd-Pb-Hf isotopes

Whole rock Sr–Nd–Hf–Pb isotope data for 17 samples (including 7 MMEs) are given in Table 3.4, Table 3.5, Table 3.6 and Table 3.7 and plotted in Fig. 3.8, Fig. 3.9, Fig. 3.10 and Fig. 3.11. Contributions from mature continental crust are apparent as I_{Sr} and $Pb_{(i)}$ are radiogenic and all the $\varepsilon_{Nd}(t)$ values are slightly enriched (-5.3 to -2.1 for host rocks and -5.2 to -2.2 for MMEs). I_{Sr}, $Pb_{(i)}$, $\varepsilon_{Nd}(t)$ and $\varepsilon_{Hf}(t)$ refer to the age corrected values and ε_{Nd} and ε_{Hf} refer to the present-day values.

Theoretically, Hf and Nd isotopes are expected to correlate with each other (thus explaining the mantle array, Chauvel et al., 2008) because of the similar behavior of Lu–Hf and Sm–Nd systems during magmatism. However, it has been found that 'Nd' and 'Hf' can isotopically decouple in some circumstances (Bizimis et al., 2004, Schmitz et al., 2004 and Hoffmann et al., 2011). In our study, the majority of $\varepsilon_{Hf}(t)$values are positive (Table 3.6) indicating a significant mantle input, which is apparently inconsistent with the suggestion of negative $\varepsilon_{Nd(t)}$. Note that there are broad Lu/Hf vs. $^{176}Hf/^{177}Hf$ and Rb/Sr vs. $^{87}Sr/^{86}Sr$ correlations, but no Sm/Nd vs. $^{143}Nd/^{144}Nd$ correlation. This observation, combined with the decoupling between ε_{Nd} and ε_{Hf} could put Nd isotopic data quality into question. For this reason, we have randomly reanalyzed 5 samples for Nd isotopes and the reproducibility is good (< 66 ppm; Appendix D). The apparent non-correlation between Sm/Nd and $^{143}Nd/^{144}Nd$ can be explained by the small range in $^{147}Sm/^{144}Nd$ ratios among our samples and the long half-life of ^{147}Sm, which taken together prevent a statistically significant isochron developing in 250 Ma (Fig. 3.8C). On the contrary, the large Lu/Hf variation of up to 500% and the short half-life of ^{176}Lu explain the significant Lu/Hf psedochron.

Nevertheless, it is necessary to consider the potential effect of incomplete digestion of zircons in these samples. For example, our Teflon beaker digestion method for isotope analysis cannot digest zircons completely for the zircon-rich granitoid rocks we study. This can cause problems as > 95% Zr (see partition coefficients of Zr; Fujimaki, 1986) resides in zircons in zircon rich granitoids. If no zircons were dissolved during digestion and assuming all the Hf resides in zircons, the analyzed Hf

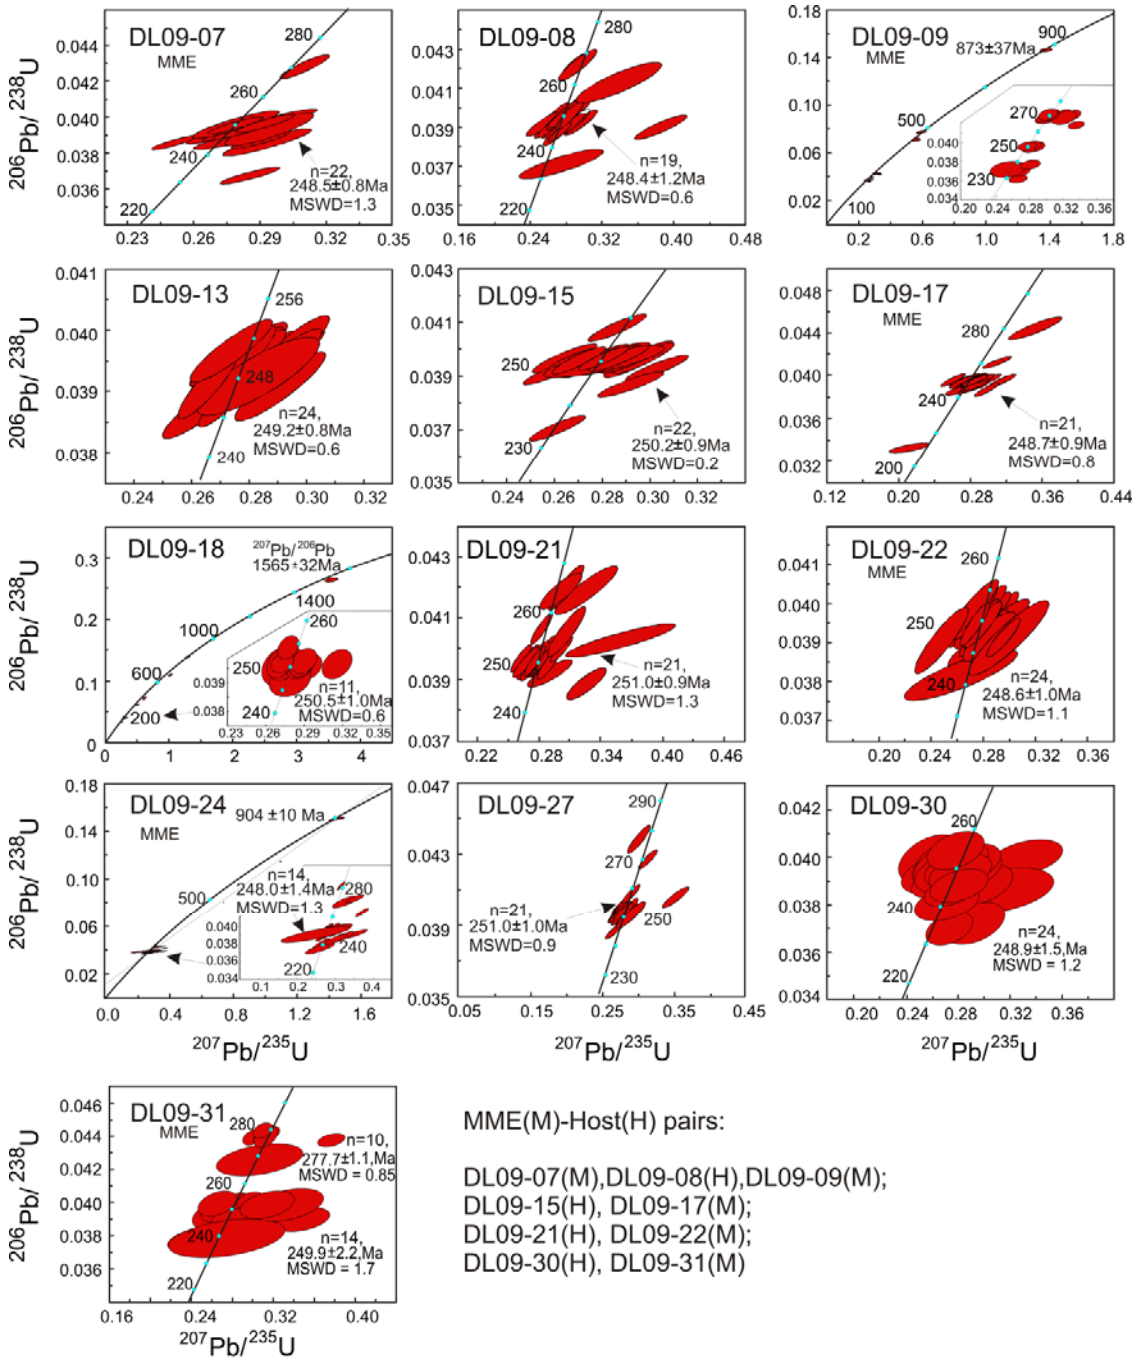

Fig. 3.7. Zircon U-Pb Concordia diagrams. The majority of zircons give ~ 250 Ma crystallization age for both granitoid hosts and the MMEs. Various amounts of inherited old zircons contained in hosts and enclaves indicate the presence and involvement of old crustal material.

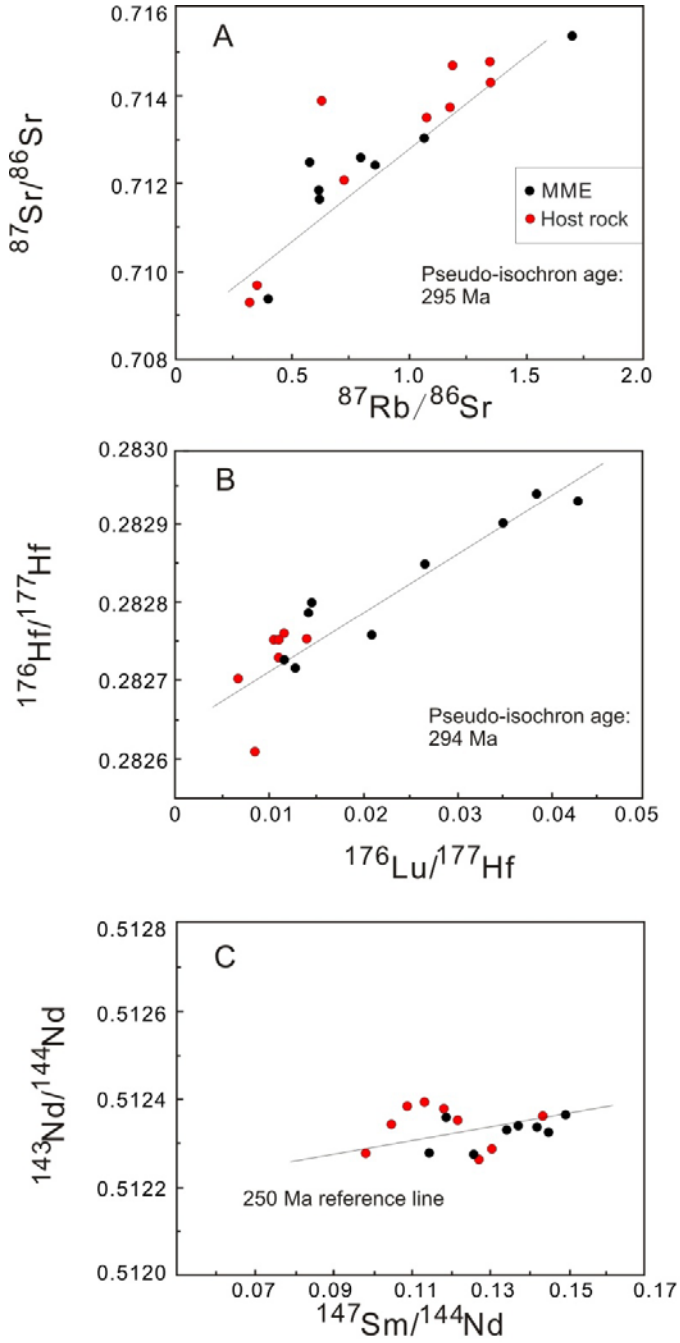

Fig. 3.8. A and B, Plots of isotope ratios vs. parent-daughter ratios, giving Rb/Sr pseudo-isochrone age of 295 Ma and Lu/Hf pseudo-icochron age of 294 Ma, which are close to the zircon *in situ* dating age of ~ 250 Ma of the EKOB granitoids. C, no correlation between $^{143}Nd/^{144}Nd$ and $^{147}Sm/^{144}Nd$. The 250 Ma reference line is shown to demonstrate the small ingrowth of radiogenic Nd isotopes.

must then be Lu decaying product in the non-zircon phases only (Fig. 3.8). However, this is unlikely to be the case for two reasons: firstly, the digestion using Teflon beakers is able to dissolve zircons to some extent, and thus the Hf hosted in the dissolved portions of zircons will enter the solution accordingly; secondly and importantly, the average size of zircons in the studied samples is 100–200 μm (Fig. 3.6), yet the rock powder particle size is ≤ 50 μm (mostly < 5 μm), i.e., the zircon fragments of ≤ 50 μm size in the solution must be well-exposed with enhanced surface areas, facilitating acid dissolution and digestion. This means that even if zircons may not be completely digested using our Hf-isotope procedure, significant portion of zircons must be digested and analyzed, with the obtained $^{176}Hf/^{177}Hf$ ratios likely approaching the bulk-rock ratios. This is demonstrated by the Lu/Hf pseudochron (Fig. 3.8B), where the $^{176}Lu/^{177}Hf$ ratio was obtained through ICP-MS trace element analysis of complete sample digestion (see above).

Therefore, the apparent decoupling of Nd isotope with Hf (and Sr) isotopes is significant, and the age-corrected initial Hf–Nd–Sr isotopic ratios can be reliably used to trace magma sources and processes.

3.4. Discussion

3.4.1. Isotope constraints on the formation of MMEs

I-type granitoids usually contain various amounts of MMEs (Holden et al., 1987 and Winter, 2010). The origin of the MMEs can hold clues to the petrogenesis of the entire granitoid–MME systems, yet the origin remains debated. For example, MMEs have been interpreted as restites (Chappell et al., 1987 and Chappell et al., 1999); as representing mantle derived melts (Barbarin, 2005, Mo et al., 2007b, Yang et al., 2007 and Clemens and Stevens, 2011); or as mafic cumulate (Wall et al., 1987, Dahlquist, 2002 and Niu et al., 2013). In the case of the EKOB, MMEs were interpreted to represent

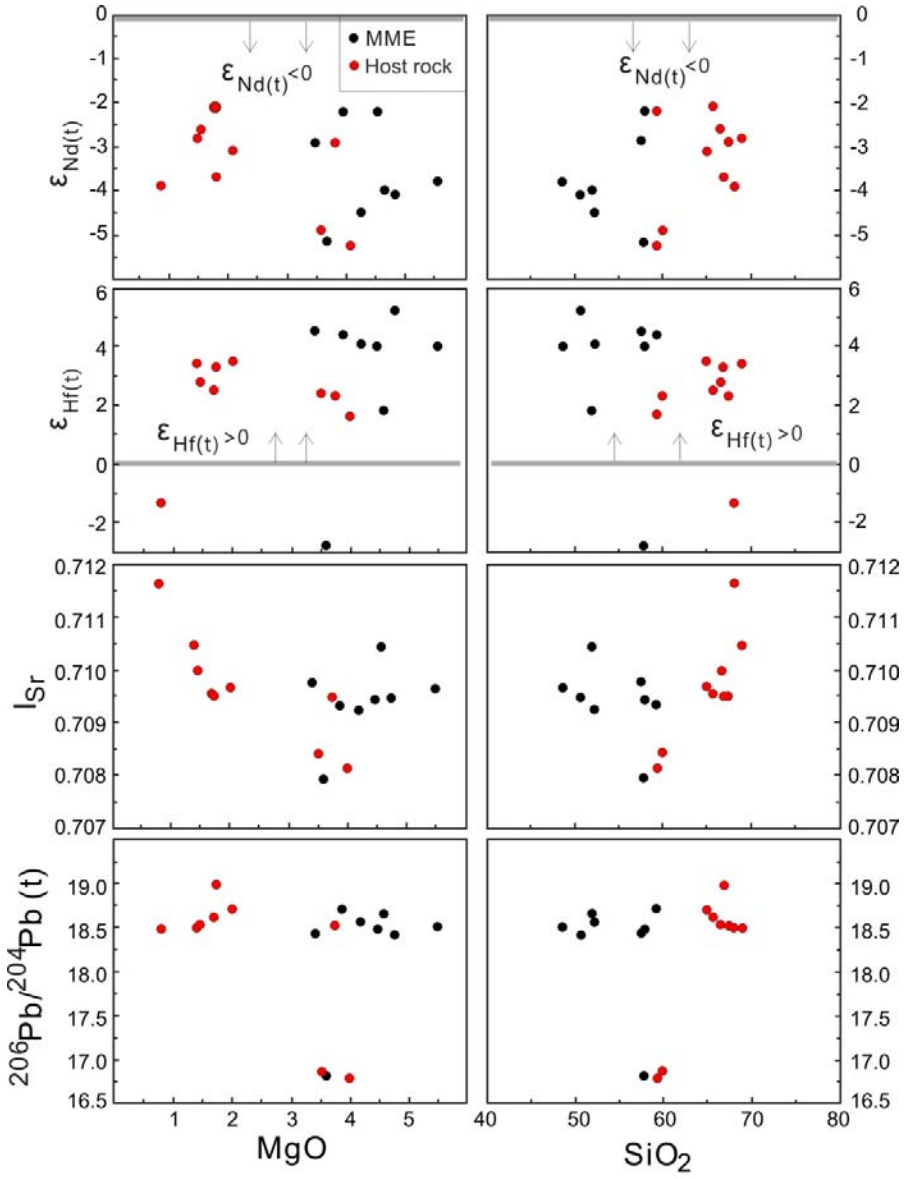

Fig. 3.9. Isotopes versus MgO and SiO_2 plots showing overlapping isotopes between MMEs with higher MgO/lower SiO_2 and the granitoid hosts with lower MgO/higher SiO_2. The negative $\varepsilon_{Nd}(t)$ values are suggestive of the crustal contribution while the dominant positive $\varepsilon_{Hf}(t)$ values are suggestive of mantle input.

mantle melts involved in magma mixing because of their mafic composition. Nevertheless, their negative $\varepsilon_{Nd(t)}$ and relatively radiogenic Sr and Pb isotopes (Liu et al., 2004b, Chen et al., 2011 and Xiong et al., 2011) are indistinguishable from those of the host rocks, arguing that if they

are indeed mantle melts, they must be derived from an unusually enriched mantle source (Liu et al., 2004b and Xiong et al., 2011).

It is not always straight forward to distinguish a cumulate process from a mixing process in terms of major and trace element data because both techniques can produce linear trends on Harker plots (Clemens and Stevens, 2011). In this case, isotopes are robust tools for distinguishing mantle derived magmas (MMEs) (which should be dominated by a mantle isotopic signature) from crustal melts (granitoid hosts) (which should be dominated by a crustal isotopic signature). For example, enclaves from Criffell and Strontian plutons in northern Britain consistently have higher $\varepsilon_{Nd(t)}$ than the adjacent hosts, representing the mixing process (Holden et al., 1987). Fig. 3.9 shows, however, that this is not the case in our study. MMEs do not have consistently higher $\varepsilon_{Nd(t)}$ or $\varepsilon_{Hf(t)}$ than their hosts (Fig. 3.10) but overlapping isotopic compositions and they do not show covariations with SiO_2 or MgO. Furthermore, even samples from the same host or the same enclave can have different initial isotopes, see ①, ②, ③ etc. in (Fig. 3.10). The completely overlapping initial isotopes between the host rocks and MMEs are indicative of their same origin. The initial isotopic ratio variations within individual outcrops or enclaves largely reflect small scale isotopic heterogeneity due to incomplete homogenization of melts affected by crustal assimilation or modal variation or both. This is because granitoid magmas under sub-liquidus conditions are "crystal mashes" and complete homogenization is restricted by the efficient diffusion (Ramos and Reid, 2005 and McLeod et al., 2012).

Some authors have invoked that homogenous mixing may have resulted in the overlapping Sr and Nd isotopes between MMEs and host rocks, by arguing that isotopes and trace elements diffuse faster than major elements (Mo et al., 2007b), however, this is unlikely. Indeed, elements diffuse on microscopic scales (Lesher, 1990, Allen, 1991 and Holden et al., 1991), but cannot explain macroscopic process on whole magma chamber scales with the large isotopic variations within

individual host rocks and MMEs. In contrast, the large variability within the individual host and MME indicates that the diffusion was rather limited. Several observations are indicative of

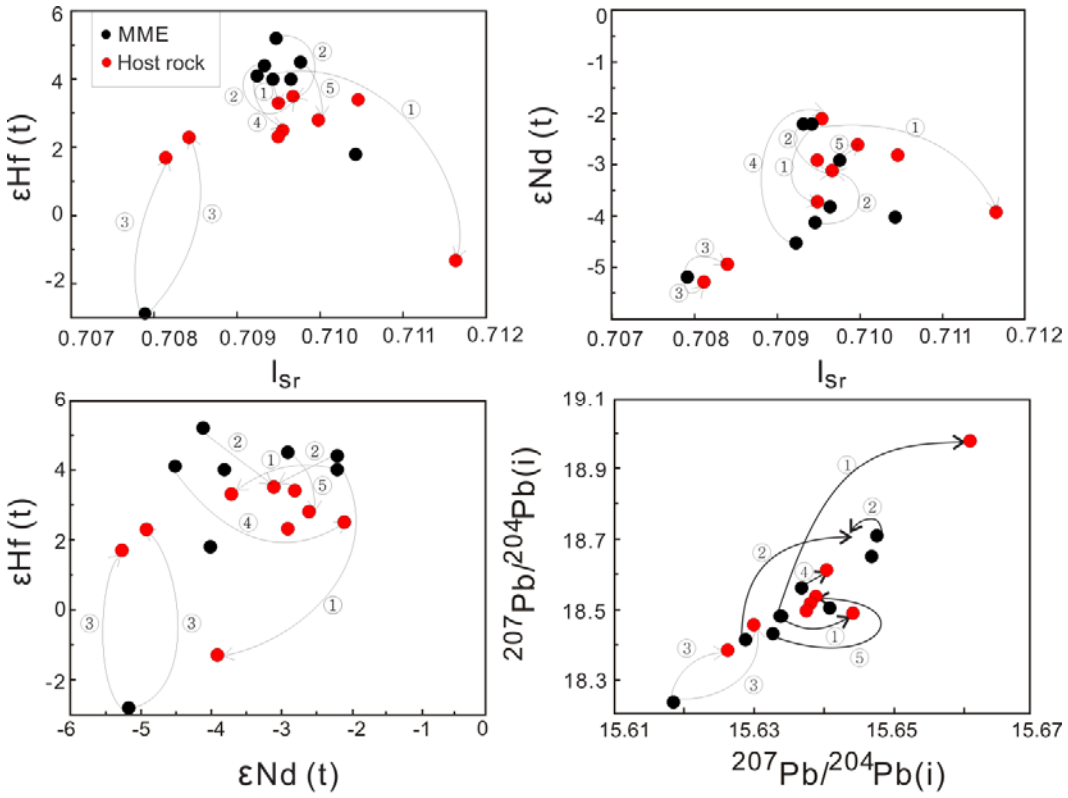

Fig. 3.10. Small scale age-corrected (250 Ma) isotope variation diagrams showing overlapping isotopes between the granitoid hosts and MMEs and isotopic variations within individual host and MME, which actually reflect magma heterogeneity (with some superimposed mineralogical differences) rather than mixing process. MME(M)-Host(H) pairs: ①:DL09-07(M), DL09-08(H), DL09-09(H) (two host rocks for the same MME); ②: DL09-15(H), DL09-16(M), DL09-17(M) (two enclaves for the same host rock); ③: DL09-30 (H), DL09-31 (M), DL09-32 (H) (two host rocks for the same enclaves). Others, ④: DL09-13(H), DL09-14(M); ⑤: DL09-21(H), DL09-22(M). H: host rock; M: MME.

cumulate origin for MMEs: (1) Mineralogically, the MMEs are the same as their hosts but differ in modal abundances (see Fig. 3.2); (2) the oval shapes and shared mineralogy imply that the MMEs were plastic and in thermal equilibrium with their hosts at the time of emplacement; (3) the coherent compositional trend on the Harker diagrams is more like liquid lines of descent (Fig. 3.4); (4) MMEs have higher abundances of HREEs than their respective host (Fig. S1); (5) importantly, the

MMEs and host rocks have overlapping and indistinguishable isotopes (Fig. 3.9 and Fig. 3.10). These all demonstrate that MMEs are disintegrated early liquidus mineral cumulate and then may have been disturbed by subsequent replenishment and induced magma convection in the magma chamber.

In this context, it is worth mentioning that some Sr–Nd–Pb isotope data reported for 'mafic veins' in granitoids from Yuegelu units in the EKOB have been considered as the mafic end-member during magma mixing (Liu et al., 2004b). However, these mafic veins also have the same mineralogy and same isotopes as both enclaves and hosts granitoids (Fig. 3.11). We consider these "mafic veins" to be large bodies of cumulate origin.

Magma mixing is a common process, and we do not intend to invalidate its role in the petrogenesis of the EK granitoids. However, our observations suggest that caution is necessary when invoking 'magma mixing' without a thorough consideration of the data.

3.4.2. **Geochemical constraints on the source**

Our Sr, Pb and Nd isotope data set is in agreement with previous results (Liu et al., 2004b) showing radiogenic Sr and Pb and slightly radiogenic Nd isotopes, which indicate possible contributions of continental crustal materials, whereas the notably positive $\varepsilon_{Hf}(t)$ values are indicative of juvenile crustal materials and argue for significant mantle input. As the crustal contamination during melt emplacement is inevitable, the $\varepsilon_{Hf}(t)$ values in the parental melt would thus have been underestimated and thus should be more positive pointing to even stronger mantle signatures. To produce large volumes of andesitic batholiths with mantle isotope signature, a basaltic source is required (Mo et al., 2008). In this case, oceanic crust is the most probable candidate because it can impart its inherited mantle isotopic signatures to the derivative melt (Niu, 2005, Tatsumi, 2006, Mo et al., 2008 and Niu and O'Hara, 2009). The subducted oceanic crust may be from the A'nyemaqen

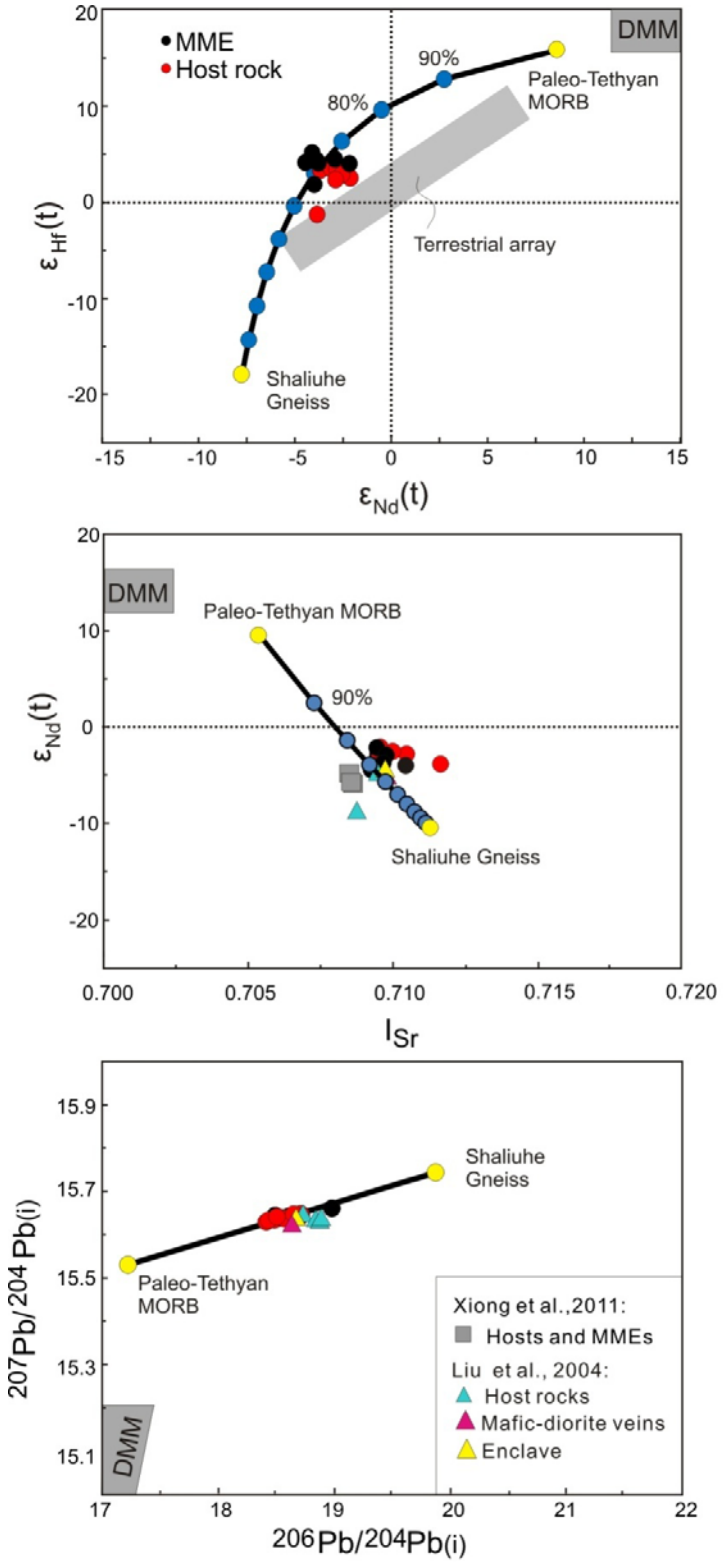

Fig. 3.11. Showing that the mafic enclaves (MME), host rocks in this study and mafic-diorite veins in the literature (Liu et al., 2004b; Xiong et al., 2011.) all have indistinguishable isotope compositions and they plot along an apparent 'mixing' trend between Paleo-Tethyan MORB and terrestrial sediments (the Shaliuhe gneiss). Terrestrial array is from Chauvel et al., (2008). Sr, Nd and Pb isotopes and elemental concentrations for Paleo-Tethyan MORB are from the east part of the northernmost branch of the Paleo-Tethyan realm ($^{87}Sr/^{86}Sr$:0.7055, $^{143}Nd/^{144}Nd$:0.51313, $^{206}Pb/^{204}Pb$: 17.257, $^{207}Pb/^{204}Pb$:15.532, Sr: 69.07ppm, Nd: 6.5ppm, Hf: 1.87ppm, Pb: 1.91ppm) (Xu et al., 2002). Hf isotope for MORB is inferred from Nd isotope following the equation ($\varepsilon_{Hf}=1.59\varepsilon_{Nd}+1.28$) given by (Chauvel et al., 2008) because of the statistically significant Hf-Nd isotope ratio correlation (Zindler and Hart, 1986). Sr isotope ($^{87}Sr/^{86}Sr$: 0.7180, Sr: 300ppm) for the Shaliuhe Gneiss is from Harris et al., (1988a). Nd and Pb isotope data ($^{143}Nd/^{144}Nd$:0.5121, $^{206}Pb/^{204}Pb$: 20.000, $^{207}Pb/^{204}Pb$:15.750, Nd: 33ppm, Pb: 19.50ppm) for the Shaliuhe Gneiss are from Chen et al., (2007b) and Meng et al., (2005a). Hf isotope data ($^{176}Hf/^{177}Hf$: 0.28218, Hf: 4ppm) for the Shaliuhe Gneiss are from Chen et al., (2007c). Grey Square: Host rocks and enclaves from (Xiong et al., 2011). Triangle: host rocks, enclaves and mafic veins from (Liu et al., 2004b)

Ocean, which is a branch of the Paleo-Tethyan that started opening around 308 Ma (Yang et al., 2009). The subducting/subducted materials comprise at least two chemically different components: altered basaltic oceanic crust and more silicic sediments (Tatsumi, 2006). The incompatible elements are depleted in the oceanic crust produced at ocean ridges but can be significantly enhanced through hydrothermal alteration and sea floor weathering especially with the involvement of terrigenous sediments of upper continental crust origin (Niu, 2005 and Niu and O'Hara, 2009).

In Fig. 3.11, the EKOB granitoid isotope data plot along an apparent "mixing" trend between the Paleo-Tethyan oceanic crust (represented by the 350 Ma ophiolitic MORB in Qinling, central China; Xu et al., 2002) and continental crustal compositions (terrigenous sediments represented by the Shaliuhe gneiss; Meng et al., 2005a). The high $\varepsilon_{Hf(t)}$ can be reasonably well modeled by melting of the Paleo-Tethyan MORB along with the subducting/subducted terrigenous sediments of Shaliuhe gneiss composition. The apparent decoupling between Nd and Hf isotopes is caused by the large difference in Nd/Hf ratios between the sediment and the oceanic crust which makes the mixing line highly curved and shift away from the terrestrial array (Fig. 3.11). In terms of Hf-isotopes, mass balance requires ~ 58–77% mantle contribution (i.e., the Paleo-Tethyan MORB), i.e., ~ 23–42% (Table 3.6) terrigenous sediments (i.e., the Shaliuhe gneiss); and requires ~ 60–74% mantle contribution in terms of Nd isotopes (Table 3.5). The Shaliuhe gneiss in the EKOB is dated at 920 Ma and has a metamorphic age of 400–500 Ma (Zhang et al., 2003b, Meng et al., 2005b and Chen et al., 2007a). The ~ 400–500 Ma granitoids are also present in the EKOB. These two time periods are consistent with the ages of inherited zircons, implying that they were both involved in the 250 Ma magmatism. Terrigenous sediments melted alongside oceanic crust also result in the isotope heterogeneity (see above) and radiogenic Sr and Pb isotopes. Despite the substantial proportion of mantle materials indicated by the isotopic compositions, the EKOB parental magmas were likely derived from partial melting of subducting oceanic crust rather than

ascending asthenospheric mantle as proposed by Luo et al. (2002). The latter would produce basaltic rather than granitoids melts.

3.4.3. Mechanism and conditions of Paleo-Tethyan oceanic crust melting

In the pioneering studies, the trace elements for 260–240 Ma intrusions in the EKOB indicate either a post-collisional setting or an active arc (Harris et al., 1988b). But Harris et al. (1988b) emphasized that the large long-lived magmatism required to produce such huge batholiths is more likely to occur in an active arc setting rather than a syn/post-collision setting (Harris et al., 1988b). It has been accepted since then that the period of 260–240 Ma is subduction-related. However, this interpretation did not carefully consider the stratigraphic records. The late Permian molasse (Jiang et al., 1992, Zhang et al., 2004 and Li et al., 2008) indicates that the onset of collision had happened at the late Permian. Also the angular unconformity between the upper-Permian to lower-Triassic marine strata and lower-Permian terrestrial strata in the EKOB (Jiang et al., 1992 and Li et al., 2008) represents a continental uplift event. Considering the strata records, the 260–240 Ma batholiths can be interpreted more precisely as syn-collisional intrusions. Furthermore, Mo et al. (2008) already demonstrated that syn-collisional magmatism is capable of producing volumetrically significant granitoid batholiths. Therefore, we argue that these granitoids were produced in a syn-collisional setting.

More and more geochemical and petrological observations have suggested that partial melting of subducted sediment/basalt is necessary (Kelemen et al., 2003 and references therein). Partial melting of subducted young, hot slab will produce high MgO andesites (Tatsumi, 2006) or ‘adakites’ (Castillo, 2006) rather than the andesitic granitoids with low MgO. Mo et al. (2008) offer a reasonable mechanism to address this issue. In their model, when the collision begins, the subducted slab evolves along a higher T/P geotherm (solid line with arrow in Fig. 3.12) due to the retarded underthrusting rate. This allows the slab to have longer time to approach thermal

equilibrium with the prior hot active continental margin (Fig. 3.13B, see below) and finally melt when the highly altered oceanic crust and sediments intersect the solidus of hydrous basaltic/granitic solidi under amphibolite facies conditions (Fig. 3.13C). The A'nyemaqen ocean started opening in the Carboniferous (Fig. 3.13A, Yang et al., 2009) and closed during the late Permian (Zhang et al., 2004) before the collision between Songpai-Ganzi (SG) and Qaidam (Fig. 3.13B). Abundant magmatism happened during the subduction-collision time (Harris et al., 1988a) establishing a warm active continental margin environment with a geotherm of probably > 20 °C/km (> 900 °C at depths of 45 km beneath an arc; Kelemen et al., 2003) before collision (Fig. 3.13B). Following the simple calculation by Mo et al. (2008), we can expect at least 40,000–55,000 km^3 andesitic rocks produced along the 1,000 km EKOB per Myr under the amphibolite-facies conditions (Fig. 3.12). It is important to note that partial melting must have taken place under the amphibolite-facies conditions because the granitoids have flat HREE

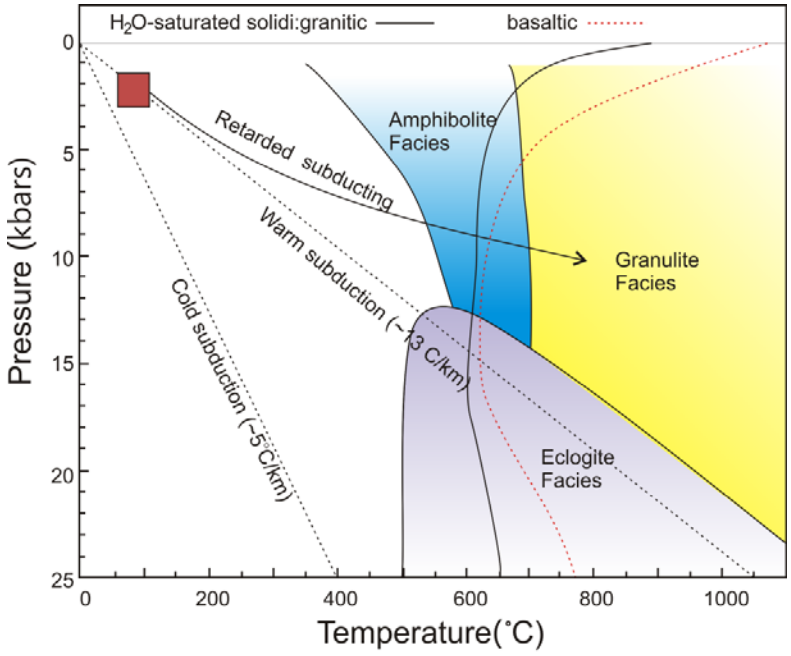

Fig. 3.12. Simplified phase diagram showing hydrous solidi of basalts and granitic rocks quoted from Mo et al. (2008; after Niu, 2005). The solid line with arrow illustrates the concept of the subducted oceanic crust (A'nyemaqen Ocean) evolve along a high T/P path as a result of retarded subducting and enhanced heating upon continental collision at a prior active continental margin setting.

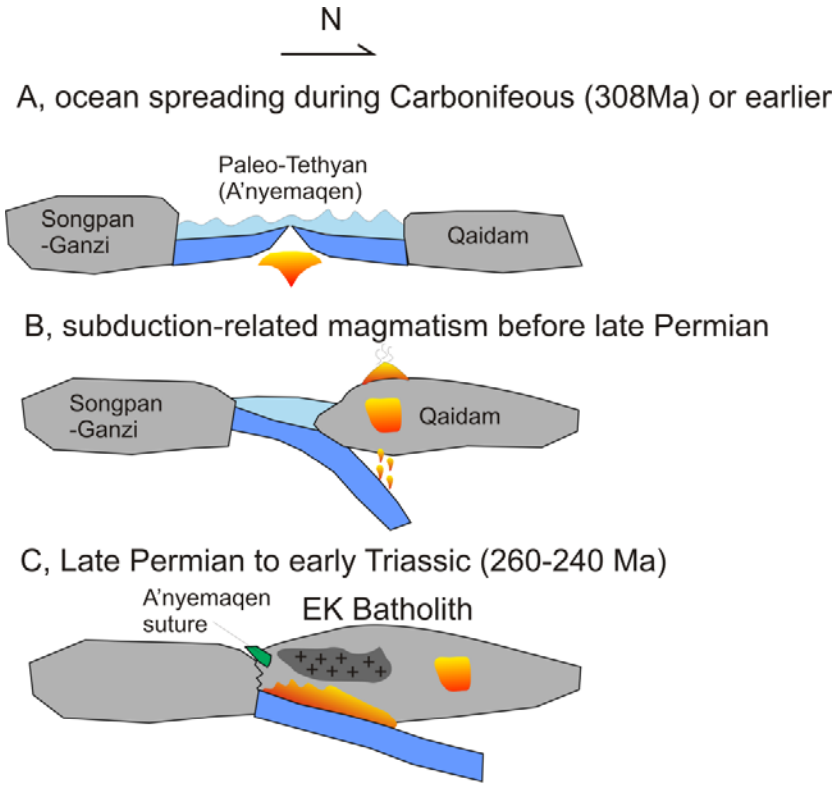

Fig. 3.13. Cartoons showing the A'nyemaqen seafloor spreading during the Carbonifeous time (A) (308 Ma: the protolith age of Dur'ngoi ophiolite (Yang et al., 2009a)), subduction of A'nyemaqen oceanic crust and related magmatism (B) and the syncollisional magmatism (C; See Figure 12 for mechanisms).

patterns (Figs. 3.5, S1) without a 'garnet signature' (Mo et al., 2008 and Wang et al., 2013). More evidence comes from zircon saturation temperature calculated from bulk rock compositions (Watson and Harrison, 1983) giving ~ 734 °C, similar to the Amp-Pl mineral thermometer ~ 737 °C (Xiong et al., 2011). This temperature is well above the wet solidus of basaltic rocks (the wet solidus is relevant because the subducting/subducted oceanic crust must have been hydrothermally altered and weathered on the seafloor) (Mo et al., 2008).

3.4.4. Continental crust growth in the collision zone

Studies of the Linzizong volcanic succession (LVS) in southern Tibet have demonstrated that juvenile continental crust is produced via partial melting of the 'trapped' oceanic crust under the amphibolite facies conditions and preserved as 'net crust growth' in the collision zones (Niu et al., 2007, Mo et al., 2008, Niu and O'Hara, 2009 and Niu et al., 2013). The syn-collisional Kunlun batholiths provide more geochemical and isotopic data to support this hypothesis. First of all, the bulk compositions of granitoids are similar to the bulk continental crust with almost identical sub-chondritic Nb/Ta, and Sr and Eu depletion (Fig. 3.5). Secondly, the whole rock Sr–Nd–Pb–Hf isotopes can be explained by partial melting of subducted Paleo-Tethyan MORB with 20%–40% terrigenous sediments of Shaliuhe gneiss composition in the melting region under the amphibolite-facies conditions (Fig. 3.11). Though the granitoids in the EKOB have relatively unradiogenic Nd isotope ($\varepsilon_{Nd(t)} < 0$) compared to the LVS, they have very positive $\varepsilon_{Hf(t)}$ values (up to 5.2), which is more convincing evidence that they are juvenile crust newly formed from oceanic crust partial melting with inherited mantle isotopic signatures and crustal/sediment contribution.

3.5. Conclusions

The Permian–Triassic batholiths (240–260 Ma) along the East Kunlun Orogenic Belt (EKOB) cover an area of ~ 20,000 km^2, representing about half of all of the intrusions. They are products of syn-collisional magmatism shortly after the Late-Permian closure of the Paleo-Tethyan Ocean (A'nyemaqen branch).

The MMEs and granitoid hosts have the same crystallization age, share the same mineralogy and contain indistinguishable isotope compositions. Therefore, the MMEs are consistent with being cumulate lithologies of more mafic compositions produced at earlier stages of the same magmatic systems derived from partial melting of the subducting/subducted oceanic crust. The isotope variations of similar range for both granitoid hosts and the MMEs are not the evidence of magma

mixing but reflect the magma heterogeneity due to the source heterogeneity and crustal contamination on varying local scales.

The large volumes of these granitoids require partial melting of a basaltic source with mantle isotopic signatures. The radiogenic Sr and Pb isotopes and slightly unradiogenic Nd isotopes indicate the input of crustal materials, while the positive $\varepsilon_{Hf(t)}$values emphasizes the significant mantle contribution. Although $\varepsilon_{Hf(t)}$ is elevated at a given $\varepsilon_{Nd(t)}$, it can be readily explained by partial melting of the subducted Paleo-Tethyan MORB alongside the terrestrial sediments represented by Shaliuhe gneiss under the amphibolite-facies condition. Both Nd and Hf isotopic modelling indicates ~ 60–80% mantle input.

The granitoids have broad compositional similarities to the bulk continental crust and have a large mantle component, thus representing newly formed juvenile crustal contributions in the EKOB. Although the closure time of the Paleo-Tethyan ocean is not well constrained, the stratigraphic records (the late-Permian molasses, the unconformity between upper-Permian to lower-Triassic and lower Permian sequences) indicate that the onset of collision was during the late Permian. Therefore, these granitoids were formed in a syn-collisional setting, and offer new evidence in support of the hypothesis that collision zones are primary sites where net continental crust is produced and preserved.

Chapter 4: The nature and history of the Qilian Block

4.1. Introduction

The Qilian Orogenic Belt (QOB) (Fig. 4.1A) within the Qilian-Qaidam system at the northernmost margin of the Greater Tibetan Plateau has recorded the histories of continental breakup, seafloor spreading, and the ultimate continental collision from the Neoproterozoic to the Paleozoic (Song et al., 2009, 2013, 2014). The tectonic subdivision of QOB has evolved over the years, and the most recent suggestion is as follows (Song et al., 2006, 2013, 2014) (Fig. 4.1A): (1) the north Qilian orogenic belt (NQOB), (2) the Qilian Block (QB), (3) the North Qaidam ultrahigh-pressure metamorphic (NQ-UHPM) belt, and (4) the Qaidam Block (QDB). The metamorphic history has been well studied and reviewed by Song et al. (2013), while the mechanism of continental growth remains unclear. For example, it is not straightforward why these two huge tectonic units (NQ-UHPM and NQOB) are spatially so close (~ 300–400 km apart; Fig. 4.1A). Several models of Qilian Orogenic Belt have been proposed (Xu et al., 1994; Yin and Harrison, 2000; Yang et al., 2002; Gehrels et al., 2003b; Song et al., 2006; Wu et al., 2006a; Xiao et al., 2009; Wu et al., 2010; Gehrels et al., 2011; Song et al., 2013, 2014). These models are debating on the location of the suture zone and subduction polarity of the Paleo-Qilian Oceanic lithosphere. However, the major hindrance is the lack of adequate knowledge of magmatism during the subduction/collision period and therefore the poor time constraints on the onset of subduction and collision. In contrast to the popular research of metamorphic rocks within the NQOB and the NQ-UHPM and numerous studies of magmatism within the NQOB, little is known about those granitoids which are coeval with metamorphism at the early Paleozoic in the QB. Sandwiched between two important tectonic units, the QB is particularly important for understanding the relationship of these subunits and the tectonic histories of the block itself and the region in the context of the Greater Tibetan Plateau evolution.

In this study, we aim to understand the nature of the Qilian Block by studying the petrology, geochronology and geochemistry of the Paleozoic granitoids with the result also having shed lights

on the evolution histories of its sutures to the north (i.e., the NQOB with seafloor subduction-zone complex) and to the south (i.e., the NQ-UHPM separating the Qaidam Block to the south).

(2013).B, Simplified geological map of the Qilian Block showing the distribution of granitoids and ophiolites (after Pan et al., 2004). Data are from the literature given in Table 4.1. C, Detailed geological map of the sampling locations (after Pan et al., 2004).

4.2. Tectonic setting and geology background

4.2.1. Strata, metamorphic rocks and mafic rocks in the QOB

The QOB is a broad and composite orogenic belt bounded by the Yangtze Craton to the southeast, East Kunlun orogenic belt to the south, Alashan Block to the northeast and Tarim Basin to the northwest (Fig. 4.1A). It has four subunits from North to South: NQOB, QB, NQ-UHPM and QDB (Fig. 4.1A, see above).

The NQOB is covered by Carboniferous to Triassic sedimentary sequences. The magmatic clasts within the Silurian flysch formations are dated at 515–429 Ma (Song et al., 2013). The Devonian molasses are also found in this belt. The NQOB is characterized by the occurrence of low-T/HP blueschist and eclogite-facies rocks (Zheng, et al., 2013). The metamorphic rocks record a cold oceanic subduction zone with a thermal gradient of ~ 6–7°C/km (Song et al., 2007; Zhang et al., 2007). There are two ophiolite belts in the NQOB (Song et al., 2013). Magmatic zircon dating for ophiolites gives ages varying from 496 to 550 Ma (Song et al., 2013) in the south and from 448 to 490 Ma in the north (Xia and Song, 2010; Song et al., 2013).

The QB, bounded by the NQOB to the north and the NQ-UHPM belt to the south is dominantly Precambrian basement (Chen et al., 2007a, 2009a, 2009b) covered with the Paleozoic sedimentary lithologies. Granitic intrusions with ages of 880–940 Ma as well as the coeval metamorphism are documented (Guo et al., 1999; Tung et al., 2007a, 2007b; Xu et al., 2007; Song et al., 2012, 2013). The Dabanshan ophiolite at the NQOB-QB boundary (Fig. 4.1B) mainly outcrops as dismembered lenses, consisting of pillow basalt, gabbro, harzburgite, pyroxenite and hornblendite etc. with minor felsic lithologies. Sm–Nd isochron gives the age of ~ 492 ± 22.6 Ma for basalt (Qinghai Geological Survey Institute, 2006). A few low-K_2O (0.05–0.96 wt%) tholeiitic dikes cut through the Paleoproterozoic basement (Qinghai Geological Survey Institute, 2006). The Lajishan ophiolite associating with tonalite, diorite and plagiogranite in the southern QB near the QB and NQ-UHPM boundary (Fig. 4.1B) is of MORB protolith and dated at 510 Ma (Hou et al., 2005).

The NQ-UHPM belt is characterized by UHPM eclogite-facies blocks and lenses hosted in the UHPM granitic gneisses (Song et al., 2003a, 2003b, 2006; Zhang et al., 2006). The protoliths of the UHPM rocks vary, including granitic gneiss of ~ 1200–900 Ma and ultramafic rocks of 550–500 Ma (Song et al., 2013; and references therein) and ~ 877–750 Ma (Yang et al., 2006; Zhang et al., 2011). Previous studies indicate that the HP-UHP metamorphism and subsequent exhumation happened from 497 Ma to 400 Ma (Yang et al., 2002; Song et al., 2003b, 2005, 2006; Chen et al., 2009a, 2009b). Volcanic arc basalts of 514 Ma are regarded as reflecting seafloor subduction (Shi et al., 2004).

The QDB is dominated by the Precambrian meta-crystalline basement (Chen et al., 2011) covered with Paleozoic-Mesozoic sedimentary rocks. It is located to the northwest of the numerous East Kunlun batholiths of Paleozoic to Mesozoic ages (Chen et al., 2011; Huang et al., 2014).

4.2.2. Paleozoic granitoids in the QOB

The Paleozoic granitoids in the QOB are concisely summarized in Fig. 4.1B and Table 4.1. Generally, I-type rocks (453–512 Ma) predate S-type rocks (424–516 Ma) despite some ages overlap (Table 4.1). They have been interpreted as products in response to varying stages of earlier southward subduction of the Qilian Ocean seafloor underneath the NQOB and later northward subduction underneath the Alashan Block, i.e., the double subduction model (Wu et al., 2006a, 2010) compared to the northward subduction model (Xu et al., 1994; Yin and Harrison, 2000; Song et al., 2013, 2014) and southward subduction model (Gehrels et al., 2003b).

There has been only one study on the Paleozoic batholiths in the QB (Yong et al., 2008). It is a typical S-type batholith of ~ 446–450 Ma in the Huangyuan (HY) area in the eastern part of the QB (Table 4.1, Fig. 4.1B) with $\varepsilon_{Nd}(t)$ of -5.2 and -6.6 (Yong et al., 2008). It is interpreted as derived from metagreywack in a syncollisional setting without giving details (Yong et al., 2008).

Granitoids in the NQ-UHPM are generally I-type before 446 Ma and S-type after 446 Ma (Fig. 4.1B, Table 4.1). The I-type granitoids are interpreted as subduction related and S-type rocks are interpreted as collision related (Wu et al., 2001, 2002; Gehrels et al., 2003b; Wu et al., 2007) based on their geochronology and petrology. Chen et al. (2011) report one I-type sample of 493 Ma and two S-type samples of 422 Ma in the Ulan area (Fig. 4.1B) and propose that they might have a source related to EM II based on the Sr–Nd–Pb–O isotopes, which cannot be justified.

Our samples are collected from 13 locations of several intrusions, generally representative of those in the eastern part of the Qilian Block. GPS data are given in Table 4.2. Two samples QL09-18 and QL09-19 are from an ophiolite in the Dabanshan at the boundary with the NQOB in the north (Fig. 4.1B, C, Table 4.1). Other samples with 'QL09' initials are from Huangyuan (HY) (Table 4.2) where Proterozoic sedimentary rocks dominate with some Mesozoic strata (Fig. 4.1C). Samples with 'QL10' initials are from the Gangcha area (Gcha) (Table 4.2) where Paleozoic and Mesozoic sedimentary strata dominate (Fig. 4.1C).

4.3. Methods

All the 24 samples were analysed for bulk-rock major and trace element compositions. Nine representative samples were selected for zircon U–Pb dating. at China University of Geosciences (Wuhan) following Liu et al. (2008) and China University of Geosciences (Beijing) following Song et al. (2010a). Results from both labs are consistent. The dated samples were analysed for bulk-rock Sr–Nd–Pb–Hf isotopes.

4.4. Petrology, zircon geochronology and geochemistry

Samples can be divided into three groups according to their ages, mineralogy, and geochemical compositions. Age data are given in Table 4.3. Three samples are significantly older than others: 924 Ma, 797 Ma and 503 Ma, respectively. Other samples are ~ 450 Ma I-type granitoids with no Al-rich minerals and S-type granitoids containing Al-rich minerals, e.g. garnet (Grt), muscovite (Ms)

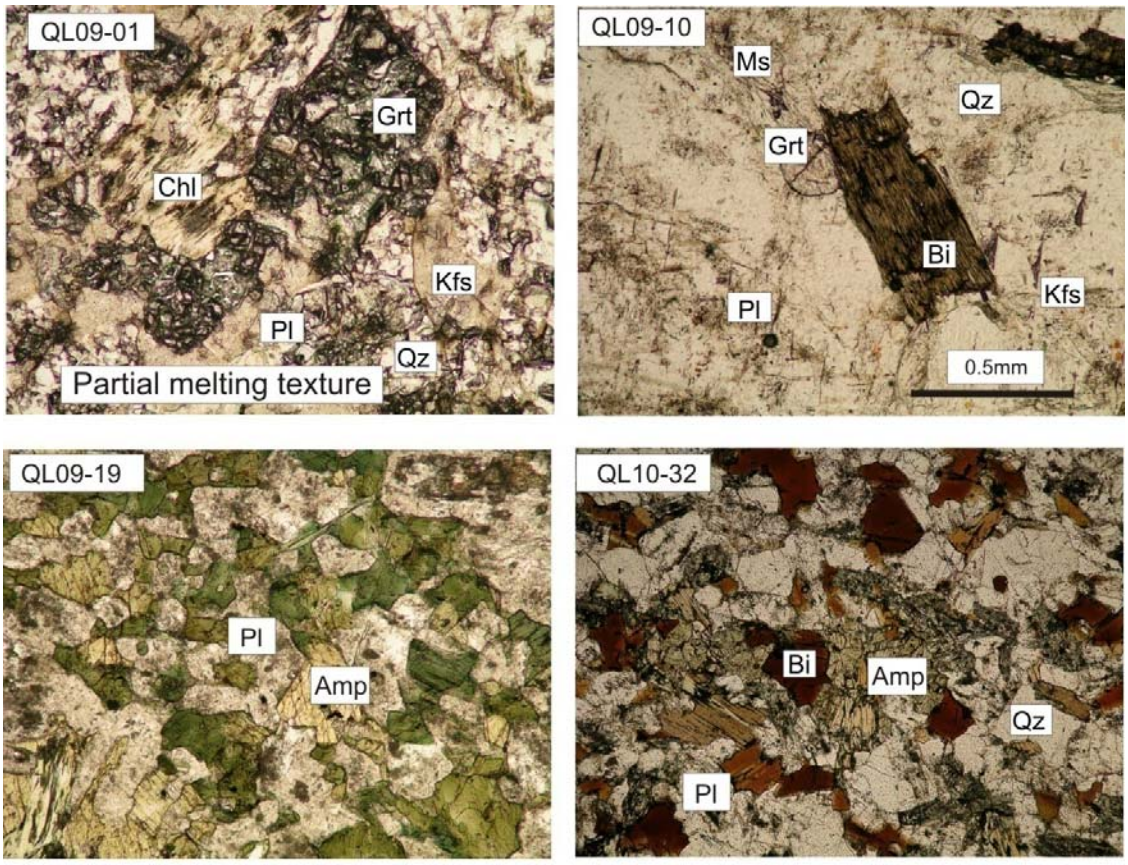

Fig. 4.2. Photomicrographs under plane polarized light showing partial melting textures of QL09-01, representative S-type granite QL09-10, I-type granite QL10-32 and enclave QL09-19 in QL09-18.

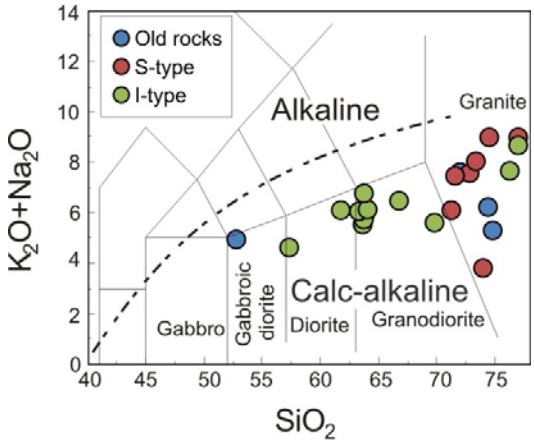

Fig. 4.3. Total alkalis (Na_2O+K_2O) versus SiO_2 (TAS) diagram showing the compositional variation of the QB samples. All the samples are calc-alkaline. The dashed line is the division between alkaline and sub-alkaline fields (Irvine and Baragar, 1971).

and allanite (Aln) (Table 4.2, Fig. 4.2). Bulk-rock major and trace element data are given in Table 4.4, and Sr–Nd–Pb–Hf isotope data are given in Table 4.5. They are all calc-alkaline (Fig. 4.3) and define good correlations on SiO_2-variation diagrams (Fig. 4.4).

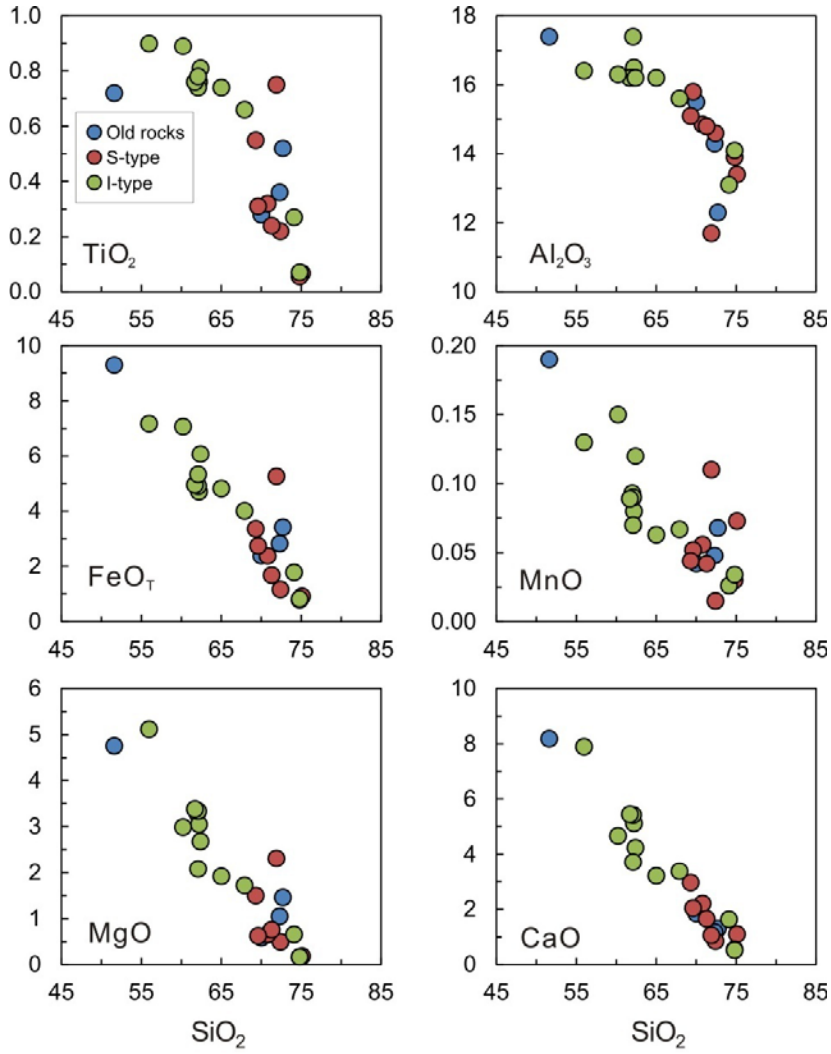

Fig. 4.4. Harker diagrams showing correlated compositional variations among samples.

4.4.1. Old rocks—924 Ma, 797 Ma and 503 Ma

Granite QL09-15 is slightly deformed, containing Qz, Pl, Kfs, and Ms. It has enriched light rare earth element (LREE) patterns with flat heavy REEs (HREEs) (Fig. 4.5). Zircons are weak luminescent and well oscillatory zoned (Fig. 4.6) with high Th/U ratios (0.18 ~ 0.49, Table 4.3).

Twenty one analyses give a coherent concordant $^{206}Pb/^{238}U$ age of 924.1 ± 1.5 Ma (Fig. 4.7), representing the crystallization age. The inherited zircons > 1.0 Ga are discordant and fail to form a Discordia line (Fig. 4.7), but these data indicate the presence of ancient crystalline rocks in the QB. The slightly negative $\varepsilon_{Nd}(924)$ value (-3.8) (Table 4.5) indicates crustal contributions which are demonstrated by inherited old zircons in this sample (Fig. 4.7). The whole-rock $\varepsilon_{Hf}(924)$ value of up to 3.8 (Table 4.5) emphasizes the significant mantle input.

Granite QL09-01consists of Qz, Kfs, Pl, Bt, Grt and Ms with partial melting texture (sieved texture, broken down minerals, vesicles, and small percentage of brown glass along grain boundary) (Fig. 4.2). It has an enriched LREE pattern with flat HREEs (Fig. 4.5). Zircon populations are complex in this sample with Th/U ratios varying from 0.23 to 1.55 (Table 4.3). Some of them display sector zoning, strip zoning, homogeneous in oval shape or clear core-mantle structure (Fig. 4.6). These grains form a Discordia line with an Archean upper intercept of 2769 Ma (Fig. 4.7). Other grains are prismatic with oscillatory zoning (Fig. 4.6) and form two populations (Fig. 4.7): concordant Paleoproterozoic age of ~ 1800 Ma (blue points of QL09-01 in Fig. 4.7) and Neoproterozoic concordant age of 796.7 Ma (Fig. 4.7). Both $\varepsilon_{Nd}(800)$ and $\varepsilon_{Hf}(800)$ are negative (-9.8 and -8.4, respectively, Table 4.5), indicating a crustal origin with less mantle input.

Granite QL09-18 has high SiO_2 (72.3 wt%) and Na_2O (5.11 wt%), low K_2O (0.97 wt%) and moderate CaO (1.18 wt%), and is peraluminous (A/CNK: 1.23) (Table 4.4). Minerals include Qz, Pl and Kfs (Table 4.2). Minor chloride occurs along the mineral boundaries and mineral cracks. It has an enriched REE pattern with a weak negative Eu anomaly and slightly upward HREEs (Fig. 4.5). Zircons are prismatic, oscillatory zoning (Fig. 4.6) and give a concordant weighted mean $^{206}Pb/^{238}U$ age of 502.9 ± 2.0 Ma (Fig. 4.7), representing the crystallization age. No inherited zircons are observed in this sample. The enclosed mafic enclave QL09-19 is composed of amphibole and plagioclase (Fig. 4.2) with 51.6 wt% SiO_2 (Table 4.4). It has similar trace element pattern to its host QL09-18 with higher elemental concentrations (Fig. 4.5A, B). Both QL09-18 and QL09-19 have

the same level of Eu anomaly (Eu/Eu* = 0.86, Table 4.4). QL09-18 carries strong mantle isotopic signature, e.g. highly positive $\varepsilon_{Nd}(503)(3.1)$ and $\varepsilon_{Hf}(503)(16.8)$, is less radiogenic I_{Sr} (0.7062) yet highest Pb isotope ratios ($^{206}Pb/^{204}Pb_i$ = 20.474; $^{207}Pb/^{204}Pb_i$ = 15.731; $^{208}Pb/^{204}Pb_i$ = 39.594) (Fig. 4.8, Table 4.5). Its mineralogy and geochemical composition resemble plagiogranite despite the apparent lack of petrotectonic constraints.

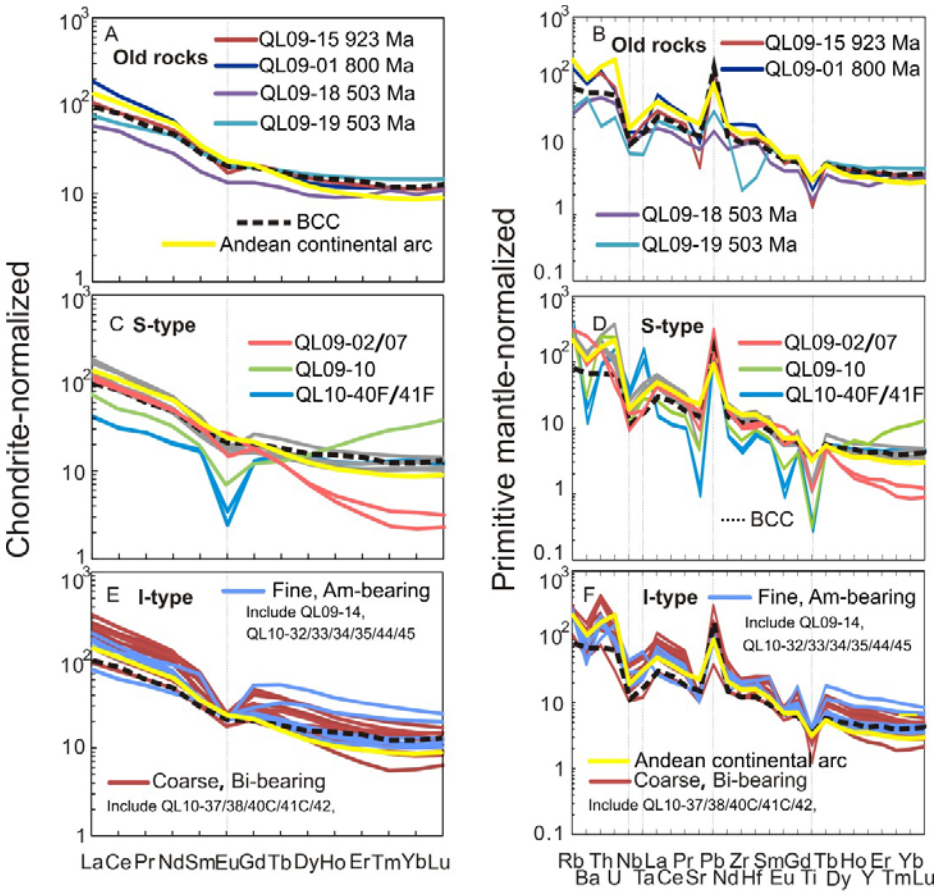

Fig. 4.5. Left column, Chondrite-normalized (Sun and McDonough, 1989) rare earth element (REE) patterns for the Qilian Block (QB) samples with varying compositions. Right column, Primitive mantle-normalized (Sun and McDonough, 1989) multi-element patterns. Majority of the samples show similar patterns resembling bulk continental crust (BCC, dash line). S-type rocks have a few exceptions: QL09-10 has upward HREEs due to the garnet. QL09-02/07 has depleted HREEs due to the garnet in the source. QL10-40F/41F are highly evolved melts. Average of Andean continental arc (yellow line) is also plotted for comparison (data from http://georoc.mpch-mainz.gwdg.de/georoc/, basaltic andesitic to andesitic compositions), which shows a large similarity to the BCC composition.

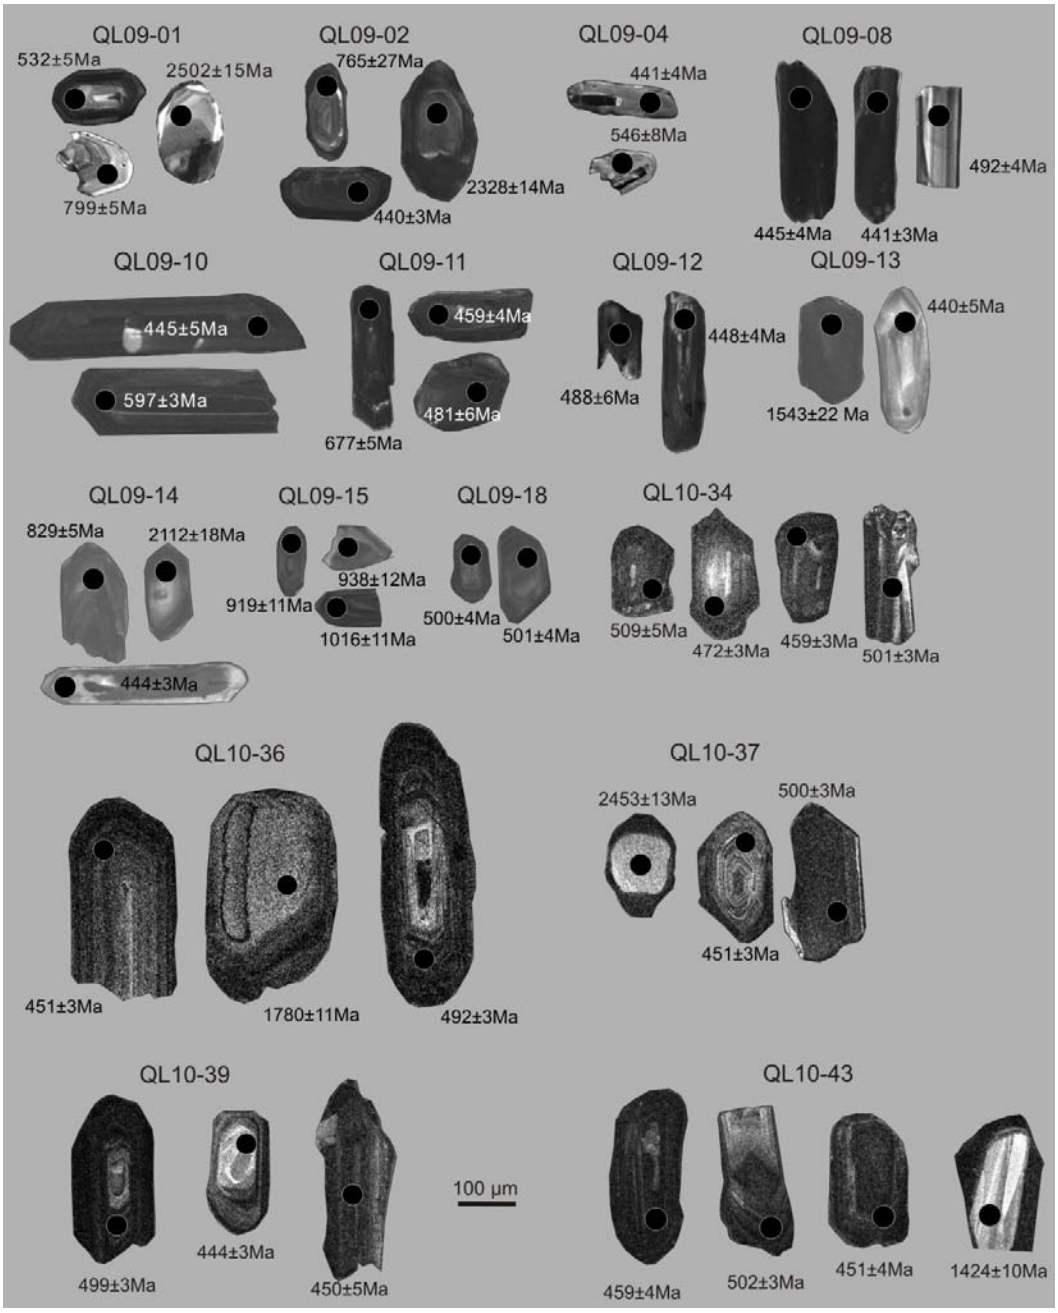

Fig. 4.6. Cathodoluminescence (CL) images of zircons from representative samples. Black circles with white outlines are analyzed spots. The numerals are ages in Ma.

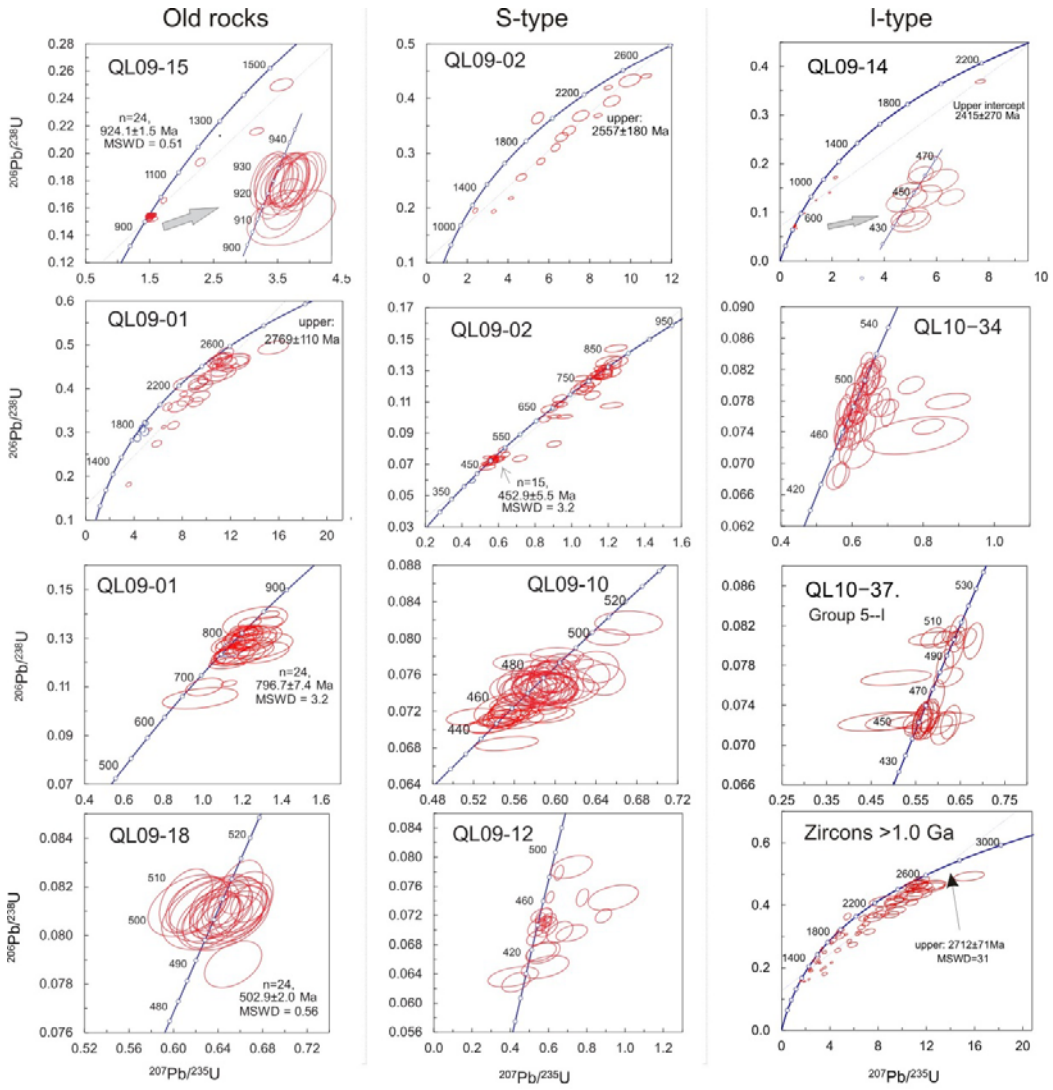

Fig. 4.7. Zircon U-Pb Concordia diagrams. Old rocks 924 Ma QL09-15, 797 Ma QL09-01 and 503 Ma QL09-18 are well dated. 450 Ma I-type and S-type rocks have large age ranges and are not well dated. We choose the youngest peak at ~450 Ma on the histogram as the emplacing time (see text).

4.4.2. ~450 Ma I-type and S-type

S-type samples (Table 4.2, Fig. 4.2) are all highly felsic (SiO_2 > 70.4 wt%) and peraluminous (A/CNK>1.17) (Tables 4.4), consisting of Qz, Kfs, Pl, Bt and Ms. They have LREE enriched patterns with dominant flat HREEs (Fig. 4.5C, D). Two-mica granite sample QL09-02 and QL09-07 are characterized by depleted HREEs (Fig. 4.5C, D), indicating the presence of garnet as a residual phase during melting in the source. Sample QL09-10 has elevated HREEs (Fig. 4.5C, D).

Two fine-grained granites (QL10-40F, QL10-41F, Fig. 4.5C, D; Table 4.2) display a 'V' shape REE pattern with low LREE abundances, a pronounced negative Eu anomaly and high abundance of Ta, resembling highly evolved melts.

I-type rocks (Table 4.2, Fig. 4.2) are fine- and coarse-grained with gradational contact between each other. Fine grained samples consist of Pl, Qz, Amp and Bt. A/CNK values are ≤1. Coarse-grained samples consist of Pl, Qz and Bt without Amp. They all show similar REE patterns (Fig. 4.5E, F), resembling the bulk continental crust signature (BCC) (Fig. 4.5) with negative Eu, Nb-Ta-Ti anomalies, a prominent positive Pb anomaly and a flat HREE pattern.

4.4.3. Ages of I- and S-type samples

Ages of >1.0 Ga are given by the zircons with distinct core-mantle structure. Zircons with ages varying from 420 Ma to 510 Ma (Fig. 4.7) do not have clear differences from each other based on trace elements (Appendix F) and texture. They are all magmatic grains showing similar structures under CL images (Fig. 4.6), i.e., oscillatory zoning, strip zoning or homogenous with Th/U ratios > 0.1 (Table 4.3). Young and old ages can be either on the rims or the centre, which rule out the possibility of cryptic core-mantle structure. The scattering concordant ages along Concordia might be common in the S-type granitoids. But the I-type samples in this study also tend to have the similar age distributions as those S-type samples do, which is neither common nor expected. The key observation is that they have large age variations; therefore, it is difficult to obtain reliable weighted mean ages with small MSWD. Theoretically, the youngest clustering group should be the crystallization age for magmatic rocks. For each sample here, zircons younger than 450 Ma are mostly plotted away from the Concordia (at least not as concordant as 450 Ma points) (Fig. 4.7). Therefore, we interpret 450 Ma as representing the emplacement time, which is consistent with zircon age peaks on the histogram (Fig. 4.9, $^{206}Pb/^{238}U$ ages with > 90 % concordance for zircons <1.0 Ga and $^{207}Pb/^{206}Pb$ ages with > 85 % concordance for zircons >1.0 Ga are plotted). The inherited zircons in these ~ 450 Ma rocks correspond to the ages of aforementioned older rocks and

their inherited zircons. Especially QL09-02 has almost the same inherited zircon distribution as QL09-01(Fig.4.7), e.g. Archean upper intercepts and inherited zircons of ~ 800 Ma in QL09-02 are coherent with the age of QL09-01.

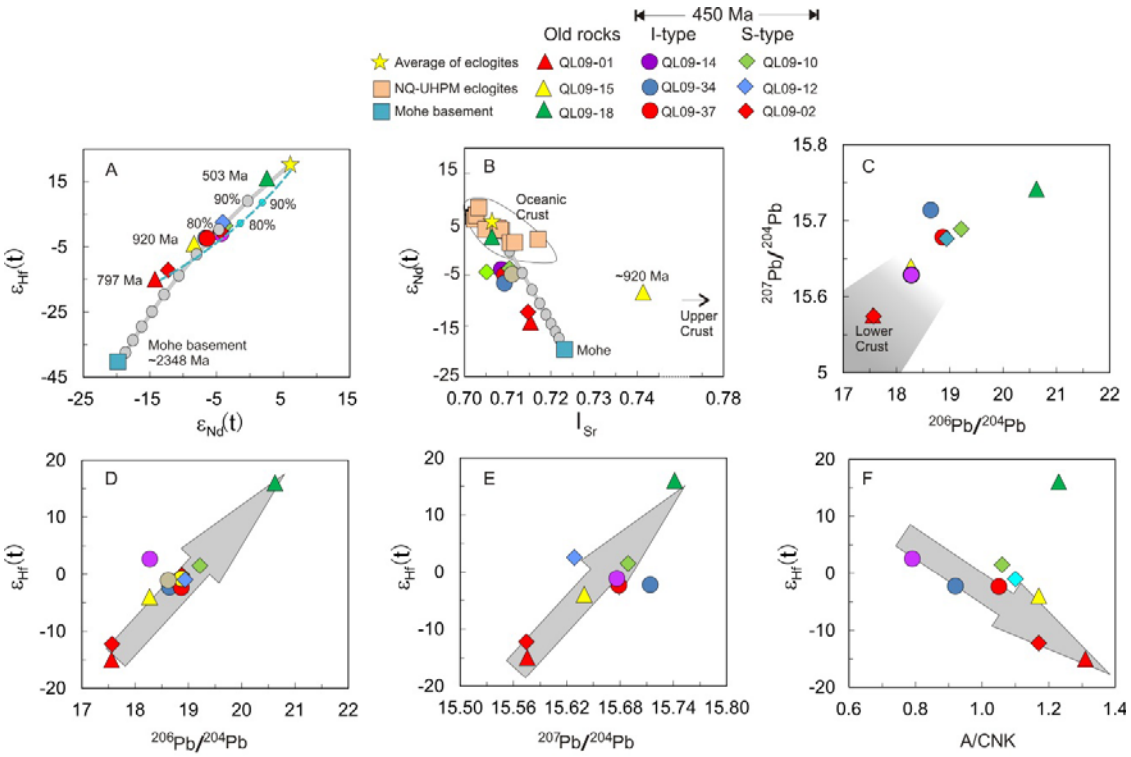

Fig. 4.8. Isotope plots with all the samples (including 923 Ma, 797 Ma, 503 Ma and 450 Ma) age corrected to ~ 450 Ma, showing significant correlations among these samples. QL09-02 has similar isotopes to 797 Ma QL09-01. The 503 Ma granite has similar isotopes to eclogites in NQ-UHPM based on the current available data for eclogites. The ~ 450 Ma granitoids are plotted on apparent 'mixing' trend (thick line in A) between eclogites (Qilian Ocean) and 2348-2470 Ma Mohe basement. Blue dash line in A is modelling using younger crustal endmember QL09-01 (797Ma, this study). Sr and Nd isotope data for eclogites are from Zhang et al. (2008). Hf isotope data for eclogitesare simply adopted global MORB composition (Workman and Hart, 2005). Hf isotope data for Mohe basement are from Li et al. (2007). Sr-Nd isotope data for Mohe basement are from Chen et al.(2007b).

Granitoids of ~ 450 Ma have overlapping isotopic compositions with small negative or positive Nd and Hf isotopes (Table 4.5, Fig. 4.8). The sample depleted in HREEs (QL09-02/07) has distinct large negative $\varepsilon_{Nd}(450)$ and $\varepsilon_{Hf}(450)$ values (-12 and -12, Table 4.5), indicating a crustal origin. Importantly, its isotopes are similar to 797 Ma QL09-01 (Fig. 4.8), most likely genetically related.

The calculated I_{Sr} for QL10-40F is smaller than 0.700, which is likely an artefact in age-correction due to high Rb/Sr (Han et al., 1997).

4.5. Discussion

4.5.1. Origin of 924 Ma and 797 Ma magmatism

Numerous granitoids of ~ 900 Ma have been reported in the NQOB, QB and NQ-UHPM belts (Guo et al., 1999; Guo and Zhao, 2000; Gehrels et al., 2003b; Zhang et al., 2003; Tung et al., 2007a; Song et al., 2012). The 924 Ma QL09-15 is similar to those in the literature (Tung et al., 2008). The small negative zircon $\varepsilon_{Hf}(943)$ (-4.7–0.21) (Chen et al., 2007c) and whole rock $\varepsilon_{Nd(943)}$ (-1.38 – -2.84) (Chen et al., 2007b) have led to the interpretation of reworked crust origin (Chen et al., 2007b, 2007c). Our whole rock $\varepsilon_{Hf}(924)$ is up to 3.8. This value is not completely against the previous interpretations but point to a significant juvenile crust component considering the obvious crustal contribution demonstrated by the inherited zircons older than 1.0 Ga (Fig. 4.7). Therefore, this sample represents a crustal growth event at ~ 920 Ma; however the exact tectonic setting is hard to conclude based only on one sample.

QL09-01 has high SiO_2 (72.7 wt%) and Al_2O_3 (A/CNK: 1.31) (Table 4.4) and negative ε_{Nd} and ε_{Hf} values ($\varepsilon_{Nd}(800)$: -9.8; $\varepsilon_{Hf}(800)$: -8.4, Table 4.5), implying its dominant reworked lower crustal origin which might be induced by the underplating mantle melt. The observation including inherited zircons (Fig. 4.7), Discordia with an upper intercept of Archean age in this study (Fig. 4.7), and the oldest basement of 2348–2470 Ma found in Qilian Block with Archean Hf isotope model ages (Chen et al., 2007b; Li et al., 2007) have particular importance that they offer the evidence of the Archean Basement underneath Qilian Block and that Qilian Block must have been a microcontinent during its journey of drift in the ancient ocean and later-on continental collisions.

4.5.2. Origin of 503 Ma granite

The strong mantle isotopic character of sample QL09-18 (ε_{Nd}(503): 3.1; ε_{Hf}(503): 17, Table 4.5) is similar to the NQ-UHPM eclogites (Zhang et al, 2008) (Fig. 4.8), and indicates that it is either directly or indirectly derived from a depleted mantle source. Though there is no direct evidence for QL09-18 as plagiogranite, we suggest the same origin for it, i.e., it was derived from extensive differentiation (up to 80% ~ 90% fractional crystallization) (Spulber and Rutherford, 1983; Floyd et al., 1998) from a low-K tholeiitic magma under hydrous conditions which is a widely used model for the petrogenesis of plagiogranite (Kay and Senechal, 1976; Flagler and Spray, 1991; Rollinson, 2009). Using the simple batch melting model, the original mantle source can be varying from slightly depleted to slightly enriched in LREEs, depending on the degree of partial melting. The problem is that extensive fractional crystallization could have resulted in the prominent negative Eu anomaly. However, the enclosed mafic diorite enclave QL09-19 representing the earlier cumulate has the identical Eu/Eu* anomaly with QL09-18. This means that fractionation of QL09-19 would have not necessarily resulted in the pronounced negative Eu anomaly in QL09-18.

4.5.3. Origin of ~450 Ma I-type and S-type granites

4.5.3.1. 'Mixing process'

The significant correlations on SiO_2-variation diagrams (Fig. 4.4) and isotope plots (Fig. 4.8) all point to an apparent 'mixing process' which is further demonstrated by positive correlations between initial Pb isotopic ratio and both ε_{Hf} and ε_{Nd} (Fig. 4.8). Importantly, ε_{Hf}(t) is negatively correlated with A/CNK (Fig. 4.8F, except QL09-18), reflecting that the more peraluminous samples have more crustal (vs. mantle) contributions as expected. The old rocks (924 Ma, 797 Ma and 503 Ma) are also plotted on the trend defined by these ~ 450 Ma granitoids (Fig. 4.8) (924 Ma sample has relatively radiogenic Sr isotopes probably due to post-magmatic modification process as it is slightly deformed). However, it is physically unlikely that these granitoids of such a wide spatial and temporal variation are derived from mixing two singular melts. The inherited zircons of aforementioned ages, e.g. 924 Ma, 797 Ma and 503 Ma, repeatedly occur in the 450 Ma rocks (Fig.

4.7). This observation, combined with the linear trends on the isotopes, suggests that these old rocks repeatedly underwent reworking processes with varying proportions of mantle input, in other words, they were essentially derived from the same source at different times.

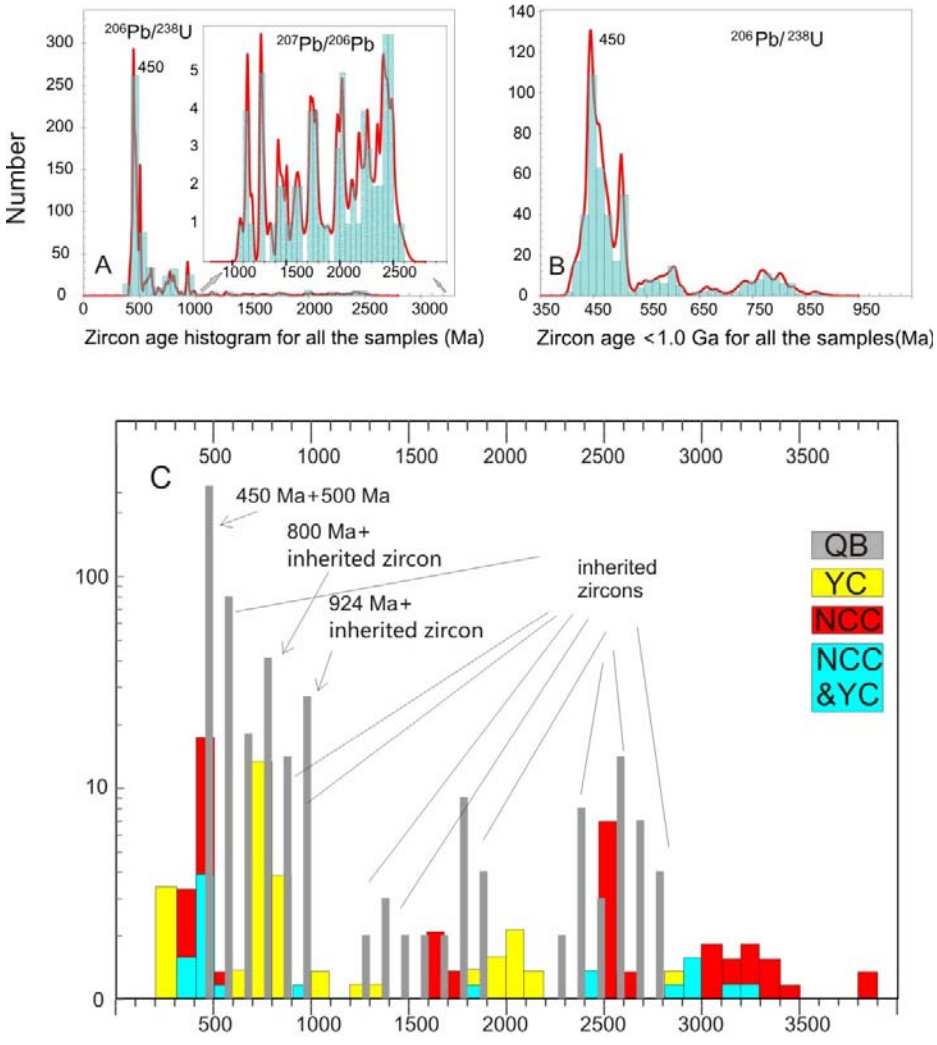

Fig. 4.9. The histogram of all the zircon ages ($^{206}Pb/^{238}U$ for ages <1.0 Ga and $^{207}Pb/^{206}Pb$ for ages >1.0 Ga). A: emphasis the inherited ages >1.0 Ga. B: emphasis the inherited ages between 700 Ma and 500 Ma. C: comparison between North China Craton (NCC), Yangtze Craton (YC) (modified after Grimmer et al., (2003)) and Qilian Block (QB) (this study).

Simple binary isotopic mixing modelling is used to constrain the source materials (Fig. 4.8). The mantle endmember is represented by the eclogites in the NQ-UHPM (yellow star in Fig. 4.8, Zhang et al., 2008) whose protolith is the ocean crust possessing the mantle isotope signatures. Although the Archean basement is involved, we choose to use Mohe basement of 2348−2470 Ma (Chen et al., 2007b; Li et al., 2007) as crustal component because it is the oldest basement with reliable Hf isotopes and inherited zircons of this age are sampled in this study. Therefore the mantle contributions herein are underestimated. The modelling requires 70% ~ 80% mantle contributions for most samples (except for samples QL09-02). This is a strong constraint that the mantle cannot be the appropriate source as 70−80 % mantle derived basalts would make the final magma basaltic rather than peraluminous granitic composition. Hence, the source candidates should be basaltic or andesitic (thus the derived melt can be andestic or granitic) and carry mantle isotopic signatures. They are possibly (1) the subducted oceanic crust, (2) the newly formed island arc crust; (3) the continental arcs. The (2) is unlikely as it is not easy to explain how to melt these topographically high level rocks that are too cold (Niu and O'Hara, 2003, 2009) to produce granitoids at depth. The earlier 'I-type' granitoids in the NQ-UHPM (Wu et al., 2001, 2007; Chen et al., 2011) could be the continental arc and it is very likely that they play a role in the origin of these granitoids evident from the zircons of > 450 Ma (Figs. 4.7 and 4.9). But continental arc alone cannot explain the large compositional variation of the 450 Ma granitoids and also lack of reliable isotope constraints. Importantly, it requires very limited crustal assimilation to maintain the dominant mantle isotope signature. Considering all the petrology and geochemistry, we suggest that the most suitable candidate is the subducted oceanic crust because (1) its derived melt is andesitic, (2) it carries mantle isotopic signatures (see Mo et al., 2008; Niu and O'Hara, 2009; Niu et al., 2013).

Because the inherited zircons in QL09-01 completely covers the range defined by all the samples, it is possible that QL09-01 alone servers as the crustal endmember which can impart its inherited zircons to the derivative melt. We also conducted modelling using 800 Ma QL09-01 as crustal

endmember. It gives similar results (60% ~ 80%) (blue dash line in Fig. 4.8A). This again demonstrates that 797 Ma QL09-01 itself is the hybrid of mantle materials and the ancient basement. Therefore, the continental basement is involved directly or indirectly and the modelling and explanation is independent of which crustal endmembers we choose.

Samples QL09-02 and QL09-07 are distinct from others in terms of less radiogenic Nd and Hf isotopes (Fig. 4.8A) and obvious depleted HREEs (Fig. 4.5) indicative of the presence of garnet as a residual phase in the source region (Defant and Drummond, 1990; Atherton and Petford, 1993; Wolf and Wyllie, 1994; Hou et al., 2012; Wang et al., 2013). Due to the prominent negative $\varepsilon_{Nd}(450)$ and $\varepsilon_{Hf}(450)$ (-12, -12, Table 4.5), the source rocks of these samples must be largely of existing crustal origin. Note that 797 Ma QL09-01 has similar isotopes (Fig. 4.8) to those of QL09-02, contain Grt and present partial melting texture (Fig. 4.2) and that QL09-02 has the same inherited zircon distribution as QL09-01 and some ages matching the age of QL09-01. These indicate that QL09-02/07 is mostly the reworking products of 797 Ma intrusions presented by QL09-01. The more felsic composition of QL09-01 than QL09-02 indicates that QL09-01 may not be the immediate source and the mantle input in QL09-02 is also inevitable as evidenced by its slightly higher $\varepsilon_{Nd}(t)$ and $\varepsilon_{Hf}(t)$ (Fig. 4.8).

To conclude, both I-type and S-type granitoids contain significant mantle derived materials despite the obvious crustal contributions. Therefore, they represent a crustal growth event at ~ 450 Ma. This study is not the only example of 'S-type' granitoids representing crustal growth. Similar samples in South China (Wu et al., 2006b) also represent the crust growth although these rocks were explained as the fast recycling of the sediments of juvenile crust.

4.5.3.2. Implications of tectonic context

The eclogites of MORB protolith in the NQ-UHPM belt (Yang et al., 2002; 2006; Zhang et al., 2008) and the mafic volcanism of MORB affinity in the Lajishan ophiolite (Hou et al., 2005)

suggest the presence of ocean basin located between the QDB and the QB (Yang et al., 2002, 2006). The granitoids in the QB and NQ-UHPM indicate the northward subduction underneath the QB. In the NQ-UHPM, eclogite facies metamorphism happened at 461–497 Ma (Song et al., 2003a; Zhang et al., 2011) which means the collision happened shortly after. The coesite-bearing zircons in the pelitic gneisses indicate that continental material underthrust to depth of 100 ~ 200 km at 420 ~ 430 Ma (Song et al., 2005, 2009). These two time slots constrain that the collision must have happened in between. However, the precise timing remains unclear**.**

As emphasized above, these granitoids are both S-type and I-type intrusions. The inherited zircons of varying age (Figs. 4.7 and 4.9) indicate the very heterogeneous source. Considering the tectonic background, the most likely tectonic setting is the transition time between subduction and collision, e.g. the onset of collision, where the oceanic crust subducting together with the continental masses including the adjacent continental arcs/crust fragments as well as terrigenous sediments (Tatsumi, 2006). These subducted more silicic components and possibly the lower crust material all contribute to the crustal proportions in the 450 Ma granitoids. Varying extents of melting of the crustal rocks which genetically derived from the same source at different times will give the 'apparent mixing' trend and the observed compositional variability of the granitoids**.** The dominant S-type granitoids thereafter (this study; Wu et al., 2002) are the products in response to the collision. The onset of the collision at ~ 450 Ma is also consistent with the exhumation at ~ 420–430 Ma (Song et al., 2005, 2009) which is normally 20–25 Myrs after the onset of continental collision for the old and strong subducting oceanic slab due to the slab break-off (van Hunen and Allen, 2011).

4.5.3.3. Melting of subducted oceanic crust

It has been demonstrated that partial melting of the last fragments of subducted ocean crust in the collision zone is necessary and possible (Mo et al., 2008; Niu and O'Hara, 2009; Huang et al., 2014). The hydrous basaltic (oceanic crust) and granitic (crustal lithologies) solidus is < 650°C at

amphibole-facies (< 40 km) (see Fig. 7 in Mo et al., 2008). This temperature can be easily achieved by the last fragments of oceanic crust because: (1) the arc crust lithosphere is hot; (2) the convergence rate is significantly reduced. Petrological estimates of P–T conditions in the lowermost crust in arcs are generally high (800–1000°C) (Peacock, 2003). Specifically, in the NQ-UHPM belt, the granulite-facies metamorphic rocks record 873–948°C at 2.0 Ga and amphibolite facies metamorphic rocks record 660–695°C at 0.7–0.9 Ga (Song et al., 2003b). Nevertheless, when the collision initiates, the convergence rate would be significantly reduced at least by 50% (Royden and Husson, 2009), which allows the last part of subducted ocean crust to have longer time to be heated up. All these demonstrate that arc crust lithosphere overlying above the mantle wedge during subduction then followed by collision is hot enough to reach ~ 800°C at 40 km depth, therefore sufficient to heat up the subducting slab to its hydrous solidus of 650°C at amphibole-facies (see Fig. 7 in Mo et al., 2008). Partial melting at amphibole-facies is not only supported by thermal permissions but also required by the trace elements as majority of the samples have flat HREE patterns without the garnet signature (Fig. 4.5), indicating garnet is not a stable phase (< 40 km, Mo et al, 2008; Huang et al, 2014).

4.5.4. Tectonic evolution

The NQ-UHPM, located south to the QB, is a better studied continental subduction complex with subducted/exhumed oceanic and continental crustal rocks. It is reasonable to suspect that there was a cold and fast previous subducting oceanic lithosphere to drag down the buoyant continental materials. The basaltic rocks and MORB protolith of eclogites in the NQ-UHPM record two episodes of seafloor spreading: 877–750 Ma (Yang et al., 2006; Zhang et al., 2011) and 550–500 Ma (Hou et al., 2005; Song et al., 2013). If these two periods refer to the same ocean basin spreading (Fig. 4.10A), the ocean must have existed for more than 370 Ma. As no ocean crust > 200 Ma has survived from recycling (Niu et al., 2003), the subduction should have initiated at 677 Ma at the latest. The problem with this model is the lack of the geological record regarded to either the

long lasting subduction-related arc magmatism after 677 Ma prior to 550 Ma or the formation of ocean crust at ocean ridges between 877–750 Ma and 550–550 Ma. Song et al. (2013) suggest that the inherited age of 710 Ma in the eclogite (Zhang et al., 2007) in the NQOB is regarded as the seafloor spreading. We partly agree but consider that it more likely records the earliest back-arc basin opening between QB and Alashan Block. The back-arc spreading at ~ 710 Ma is possible as back-arc basin extension can be shortly after the initiation of cold and fast subduction within 1 Ma (Martinez and Taylor, 2006) due to the extensive mantle wedge convection resulting from steep subduction which is comparable to the modern Mariana subduction zone. Mantle-derived 503 Ma granite might be the product in the back-arc setting. Also the back-back spreading since 710 Ma can explain the quiescence of magmatism after 710 Ma and before 550 Ma. Importantly, the abundant concordant ages younger than 450 Ma (Figs.4.7 and 4.9) could be the xenocrysts and compensate some unexposed or unsampled magmatic events during this quiescence period. These inherited ages could refer to either the oceanic crust formation or subduction-related arc magmatism. In either way, they record the magmatic events. The 450 Ma magmatism is genuinely low temperature hydrous partial melting (< 650 ºC, see above), therefore, has well preserved these xenocrystal zircons. Note that our model is different from the one proposed by Song et al., (2013, 2014). We suggest that the Paleo Qilian Ocean located between the Qaidam Block and the Qilian Block (Fig. 10A) and the whole NQOB area was the back-arc, while they think the Paleo Qilian Ocean located in the NQOB area. In our model, closure of the back-arc basin resulted in the subduction complex in the NQOB and probably has led to the secondary back-arc basin opening further north. The ~ 450 Ma granitoids are the products in response to the closure of the Qilian Ocean and the onset of the Qilian-Qaidam continental collision.

Alternatively, 877–750 Ma (Yang et al., 2006; Zhang et al., 2011) and 550–500 Ma (Song et al., 2013) could record oceanic crust of two different ocean basins, e.g. Neoproterozoic Ocean and Qilian Ocean, respectively (Fig. 4.10B) (Yang et al., 2006). The NQOB and NQ-UHPM are two

independent tectonic units due to the paired subduction at the same time around > 500–400 Ma (Fig. 4.10B) (Yang et al., 2006). This model may explain the lack of direct geological record between 877–750 Ma and 550–500 Ma. But the NQOB is a cold subduction zone (Song et al., 2007; Zhang et al., 2007) which requires the old oceanic lithosphere. In Yang's model (Yang et al., 2006), the 550 – 550 Ma ocean basin lived only for ~50 Ma, which is not old enough to induce the cold subduction. We suggest that our model is more reasonable, but still requires more geological evidence.

4.5.5. Nature of the Qilian Block

Some people consider ~ 920 Ma intrusions/gneisses are the basement of the Qilian Block (Zhang et al., 2003; Tung et al., 2007a, 2008). The Paleoproterozoic and Archean basement has to some extent been overlooked. In our study, all the inherited zircons >1.0 Ga defined a Discordia with an Archean intercept of 2712 Ma (the final panel in Fig. 4.7) which is also seen in the individual sample, e.g. QL09-01, QL09-02 (Fig. 4.7). These clearly confirm the existence of Archean basement. Especially, the isotope modelling (Fig. 4.8) emphasize the important role of Archean basement in the ~ 450 Ma magmatism. The Qilian Block must once be a microcontinent during the assembling and the breaking-up of supercontinent and experienced multiple reworking processes later on. The magmatism of ~ 920 Ma and ~ 800 Ma were previously interpreted to be related to the Rodinia assembly (Guo et al., 1999; Wan et al., 2001a, 2001b; Zhang et al., 2003; Tseng et al., 2006; Song et al., 2010b, 2013) and break-up (Zhang et al., 2003; Li et al., 2008; Song et al., 2010b), respectively. Based on our data, we can only say that 924 Ma and 797 Ma magmatic episodes are respectively crustal growth and crustal reworking processes. It has been debated that the basement of the Qilian Block has a closer link to Yangtze Craton (YC) over North China Craton (NCC) (Tung, 2007a and references therein) because of none magmatism during 0.6 – 1.6 Ga, especially 0.8 – 0.9 Ga in NCC (Fig. 4.9C, modified after Grimmer et al., 2003). Probably the most obvious conclusion from Fig. 4.9C is that the distribution of magmatism in the QB matches neither NCC nor

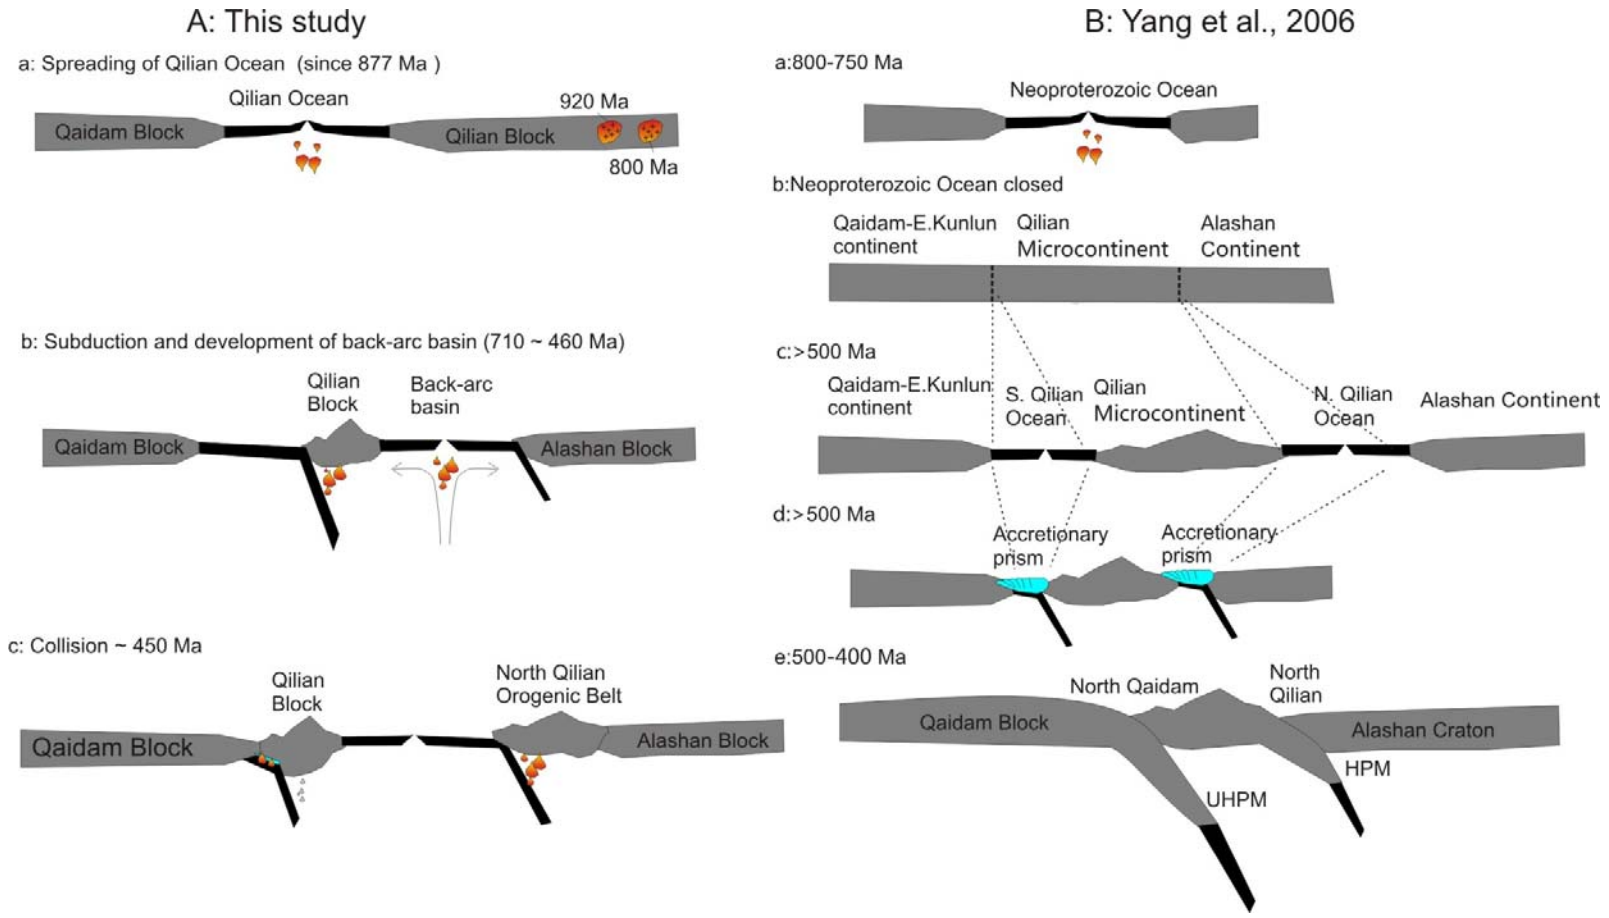

Fig. 4.10. Comparision of two models proposed by this study and Yang et al., (2006), respectively.A, this study: Cartoons showing the Qilian Ocean floor spreading between Qaidam Block and Qilian Block during the Proterozic time (a) (877 Ma: the protolith age of eclogites in NQ-UHPM (Zhang et al., 2011), initiation of subduction and related back-arc extension(b), and the syncollisional magmatism at ~ 450 Ma (c). B, Yang et al., 2006: Cartoons showing the Neoproterozoic Ocean opened and closed. Two independent Qilian oceans opened and closed during Paleozoic time. See details in Yang et al, (2006)

YC. Based on Fig. 4.9, from 1.6 Ga to Archean, the QB is comparable to both NCC and YC or maybe more closer to NCC. During 0.6 ~ 1.6 Ga, the QB and YC experienced coherent history. It might be arbitrary to say that the QB has YC affinity only because of the 0.8 ~ 0.9 Ga magmatism, especially the new finding of the ~ 0.9 Ga continental rifting magmatism in the NCC (Peng et al., 2011a, 2011b) which could be related to the 924 Ma in this study.

Chapter 5: Tectonic implications of zircon in situ Hf isotopes and whole rock Sr-Nd-Pb-Hf isotopes of Gcha and HY granitoids in the Qilian Block

5.1. Introduction

In this chapter, we discusse 7 more samples from the same sampling area as those samples discussed in Chapter 4 — Huangyuan (HY) and Gangcha (Gcha) in the QB (Fig. 5.1). In addition to the same techniques employed in the previous chapter, 5 samples in this chapter as well as 6 dated samples in the last chapter were further analysed for zircon *in situ* Hf isotopes.

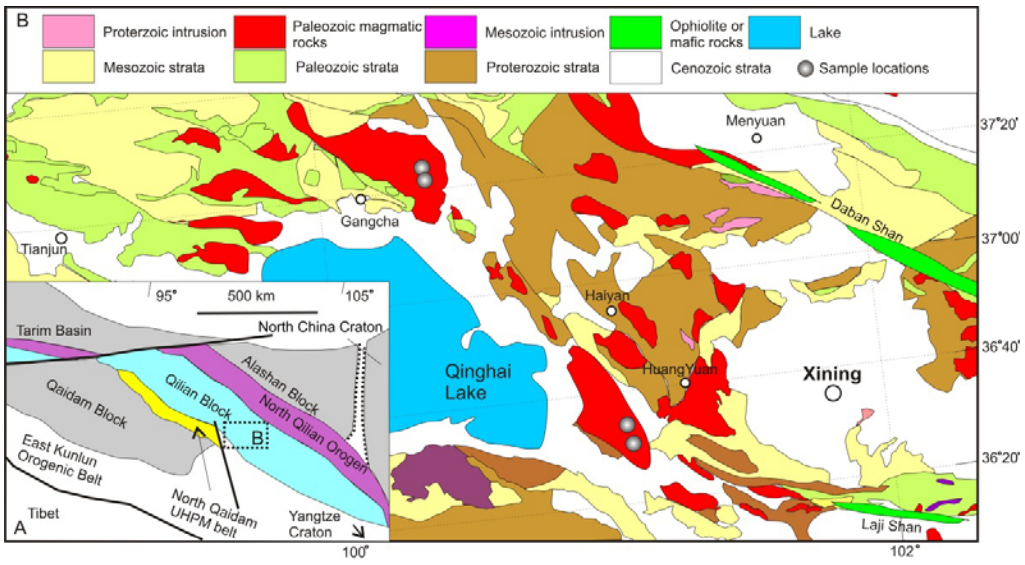

Fig. 5.1. A, Schematic map showing major tectonic units of the Qilian Orogenic Belt (after Song et al., 2013). B, Simplified geological map of the Qilian Block (QB) showing the distribution of granitoids and sampling area.

5.2. Results

Zircon U-Pb dating results for HY and Gcha samples in this chapter show the same character as samples in Chapter 4, e.g. the large age distribution along the Concordia (Fig. 5.2, Table 5.1). The ages between 420 Ma and 510 Ma cannot be subdivided into distinct populations based on textural or chemical criteria (zircon trace elements, Appendix G). The age of ~450 Ma was considered as the emplacing age for both types of rocks according to the youngest clustering concordant ages as well as the age peaks on the histogram in last chapter, However, plotting all the ages together and looking at a large resolution of the histogram, we find that the HY rocks slightly post-date Gcha rocks (~445 Ma vs. ~450 Ma, Fig. 5.3). As ages younger 510 Ma are continuous and not distinguishable from each other, we consider the ages >520 Ma as inherited ages.

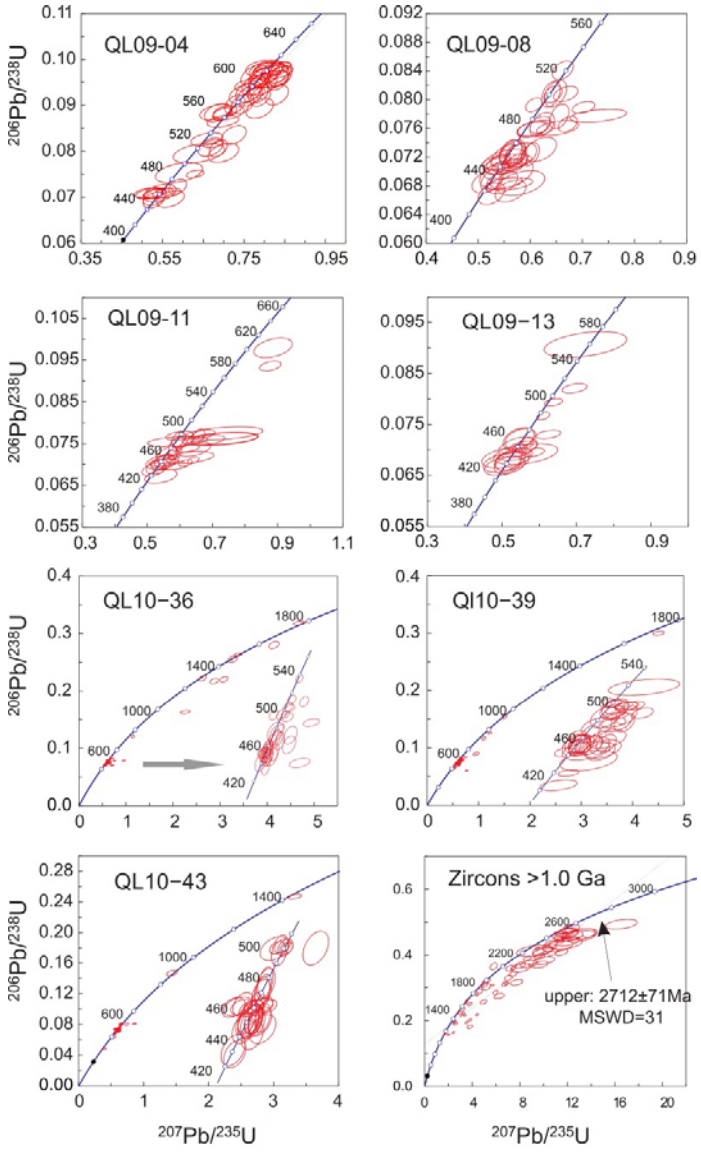

Fig. 5.2. Zircon U-Pb Concordia diagrams showing the continuous age spread along the Concordia.

HY samples in chapter 4 are mostly S-type granitoids. HY samples in this chapter are two-mica granites containing quartz, K-feldspar (>10%), plagioclase, biotite, euhedral muscovite, ±allanite. They are predominantly highly felsic (SiO_2:67.4 – 72.4 wt%) (Table 5.1). High-K and shoshonitic compositions are predominant with two of them in medium-K composition (Fig. 5.4F). Whole rock $\varepsilon_{Nd}(450)$ values range from -4.3 – -3.7 and ~ -11, corresponding to the $\varepsilon_{Hf}(450)$ values of -1.5 – 1.5 and ~ -11(Table 5.2, Fig. 5.5). Initial Pb isotopic signature is relatively radiogenic: 38.423 –38.040

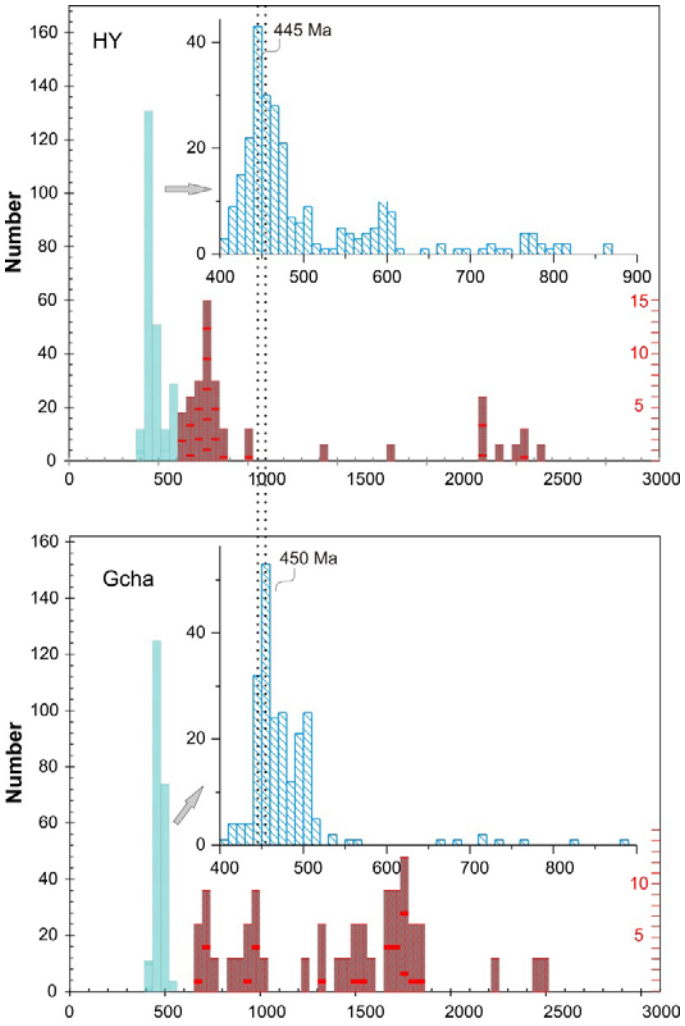

Fig. 5.3. Histograms of zircon ages for Gcha and HY rocks showing that Gcha rocks slightly predate HY rocks. The inherited zircons are shown in red with different scales (red scale on the right side).

($^{208}Pb/^{204}Pb$), 15.601 –15.686 ($^{207}Pb/^{204}Pb$), 17.702 – 19.169 ($^{206}Pb/^{204}Pb$) (Table. 5.2). Initial Sr isotopic ratios range from 0.7090 to 0.7126 (Table 5.2). Zircon *in situ* Hf isotopes at 450 Ma in HY rocks distribute a wide range, dominantly varying from -32 – 0 with a peak at -6 and a few largely negative values at ~ -60 (Fig. 5.6A, Table 5.3). The Hf isotopic variations at the zircon crystallization age are relatively limited, ranging from -30 – 10 (Fig. 5.7A). Two-stage zircon Hf model ages of HY rocks vary from 1000 Ma to 3250 Ma (Fig. 5.7C, Table 5.3).

Compared to the dominant I-type compositions in Chapter 4, Gcha samples in this chapter share the same mineralogy as some of the previous ones but possess more siliceous and peraluminous compositions (Fig. 5.4). They are biotite-granite, mainly consisting of biotite, quartz and plagioclase. K-feldspar is less than 5% and muscovite appears as a minor secondary mineral. They may present the highly evolved unit of the Gcha pluton. The high-K compositions are dominant with two of them in medium-K composition. Whole rock $\varepsilon_{Nd}(450)$ values cluster at -6.4 – -4.8 and $\varepsilon_{Hf}(450)$ values vary from -4.3 – -0.8 (Fig. 5.5, Table 5.2). Initial Pb isotopes vary from 38.335 to 38.725 ($^{208}Pb/^{204}Pb$), 15.659 to 15.676 ($^{207}Pb/^{204}Pb$), and 18.572 to 18.875 ($^{206}Pb/^{204}Pb$) (Fig. 5.5, Table 5.2). Initial Sr isotopic ratios range from 0.7116 to 0.7147, overlapping with the HY rocks.

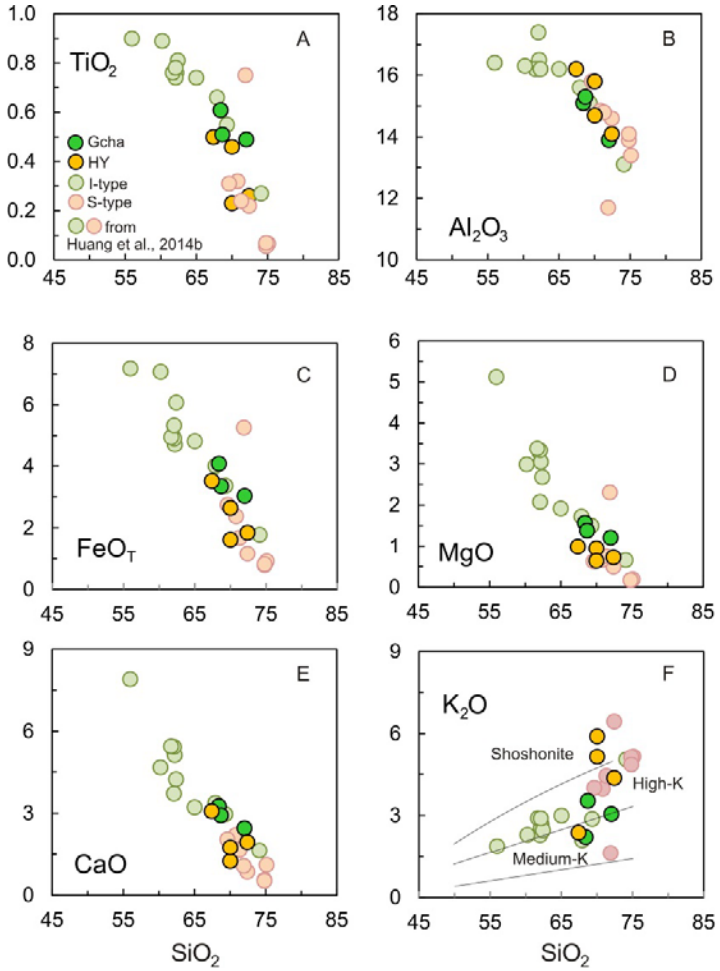

Fig. 5.4. SiO_2 variation diagrams of representative elements of I- and S-type granitoids.

Compared to HY samples, $\varepsilon_{Hf}(450)$ values for Gcha have a limited variation dominantly in the range of -6 – 0 and peak at -2 (Fig. 5.6B). Some largely negative $\varepsilon_{Hf}(450)$ values of ~ -30 and ~ -50 are also present, corresponding to those in HY rocks. If age corrected to the individual zircon crystallization ages, zircon Hf isotopes in Gcha rocks show the similar distribution as HY rocks (Fig. 5.7B), reflecting their similar sources. Two-stage zircon Hf model ages of Gcha samples vary from 1000 Ma to 3000 Ma (Fig. 5.7C, Table 5.3).

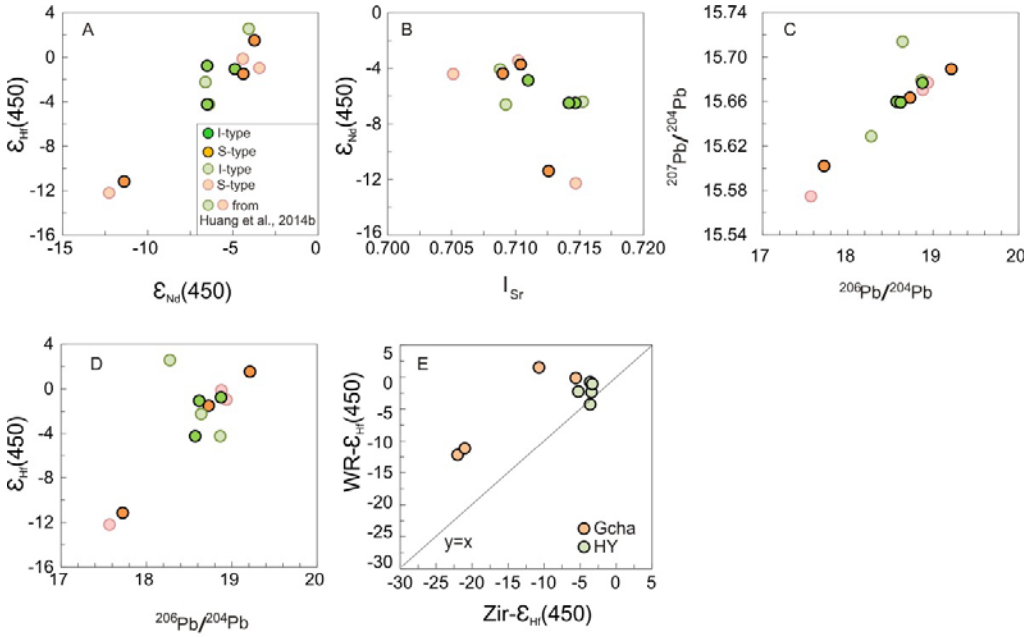

Fig. 5.5. Isotope plots show that samples in this study are plotted in the area defined by the previous study (Chapter, 4) and have good correlations (A-D). Fig. 5E shows that HY rocks have big discrepancies between whole rock $\varepsilon_{Hf}(450)$ and averages of zircon $\varepsilon_{Hf}(450)$ whereas, Gcha rocks do not.

5.3. Discussion

5.3.1. The Archean basement underneath the Qilian Block

For decades, people have considered the basement underneath the Qilian Block is of Proterozoic age on the basis of abundant ~900 Ma intrusions and gneisses. The old Mohe basement age of 2348 – 2470 Ma (Chen et al., 2007b; Li et al., 2007) has been overlooked. Chapter 4 emphasizes the presence of the Archean Basement underneath the QB based on the abundant inherited zircons as

old as 2.7 Ga (the last panel in Fig. 5.2). This notation is further supported by the zircon Hf isotope investigation in this chapter.

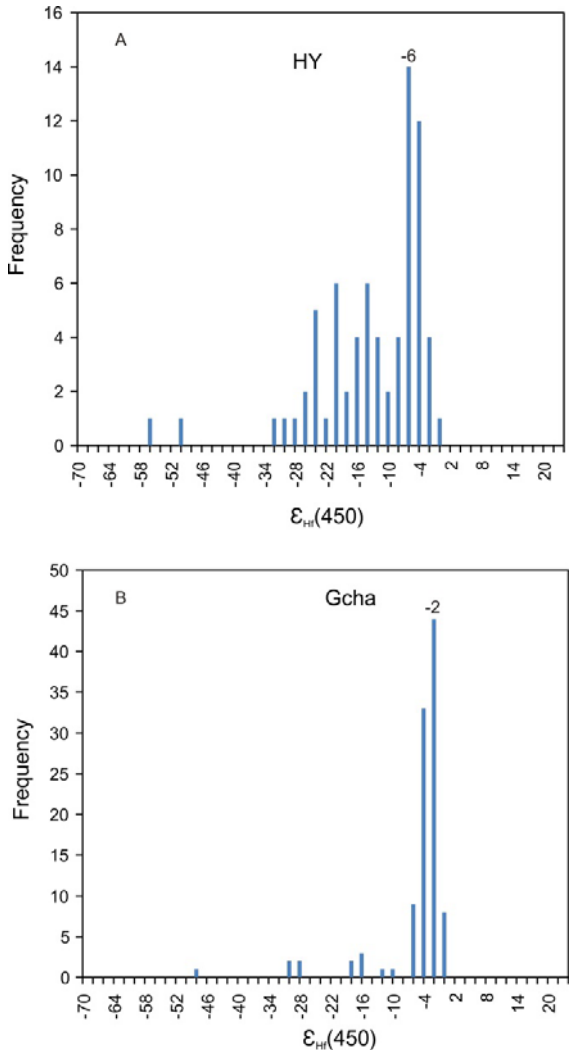

Fig. 5.6. Histograms of zircon *in situ* $\varepsilon_{Hf}(450)$ values for HY (A) and Gcha rocks (B).

Fig. 5.7C shows the zircon Hf model ages versus the zircon ages. The largely negative $\varepsilon_{Hf}(450)$ values (Fig. 5.7B) with 'crustal' model ages significantly older than 2.5Ga (Fig. 5.7C) requires the presence of an Archean basement. In this case, the Qilian Block must have served as a micro-continent during the accretion of the Qilian Orogenic belt. The presence of inherited zircons with

DMM Hf isotopes at ~1.8 Ga and ~2.5 (Fig. 5.7A) strongly indicate the juvenile crust was also formed at that time.

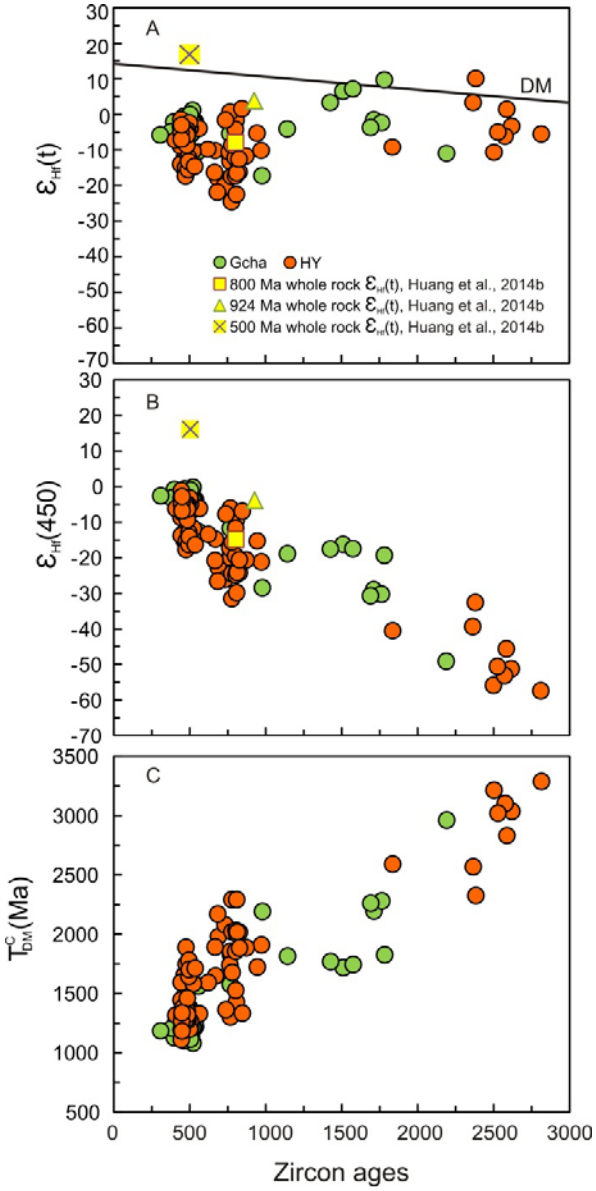

Fig. 5.7. A, $\varepsilon_{Hf}(t)$ versus the zircon ages. Ages are corrected to the individual zircon ages to show the isotopic composition of the zircons at the time of crystallization. B, $\varepsilon_{Hf}(450)$ versus the zircon ages. All ages are corrected to 450 Ma to show the source materials involved in the 450 Ma magmatism. C, Two-stage zircon Hf model ages versus zircon crystallization ages.

5.3.2. Implications for sources

Chapter 4 points out that the old intrusions of ~920 Ma and 800 Ma have been involved in the ~450 Ma magmatism because of the presence of inherited zircons of these ages in the ~450 Ma granitoids and because the whole rock Sr-Nd-Pb-Hf isotopes of old intrusions plot on the trend defined by the ~450 Ma granitoids. This interpretation is further supported by this study. The inherited zircons dated at ~900 and 800 Ma also have zircon Hf isotope composition similar to the whole rock Hf isotopic compositions of 920 Ma and 800 Ma plutons (Fig. 5.7A,B), indicating the reworking of the 800 Ma and 920 Ma crust. Fig. 5.6 shows the histogram of zircon $\varepsilon_{Hf}(450)$ values for Gcha and HY granitoids. Both of them have the same variation range, e.g. the same upper and lower limits, indicating that sources for both are the same or at least have the same isotopes. The difference between the two is that HY rocks display a considerable spread in zircon Hf isotopes (Fig. 5.6A), whereas zircon $\varepsilon_{Hf}(t)$ values for Gcha are relatively uniform (Fig. 5.6B). The limited variation of $\varepsilon_{Hf}(t)$ values (mostly within -6 – 0, Fig. 5.6B) in the Gcha rocks suggest the prominent juvenile components in the source. The relatively homogenous source for Gcha granitoids further comes from the consistence between whole-rock Hf isotopes and zircon in situ Hf isotopes (Fig. 5.5E). Whereas the HY granitoids present a much larger variation in Hf isotope (mostly -22 – 0, Fig. 5.6A) pointing to a rather heterogeneous source. The big discrepancy between whole rock Hf isotopes and zircon in situ Hf isotopes also implies that the limited and likely biased individual zircon Hf analysis cannot completely cover the whole range of the Hf isotope variation especially when the plutons are the hybrids of distinct endmembers (Huang and Niu, 2013).

According to the zircon Hf isotopes, Gcha granitoids compose more juvenile components than HY. However, whole rock Nd-Hf isotopes of HY rocks approach similar or even more radiogenic composition than Gcha rocks (Fig. 5.5A). Considering the discrepancy between whole rock Hf isotopes and zircon Hf isotopes for HY rocks, more proportions of juvenile components are required to compensate the gap, which is inconsistent with the indication by the zircon $\varepsilon_{Hf}(t)$

histogram . This inconsistence might be explained by (1) different degrees of partial melting for the same sources or (2) partial melting of sources with different maficity but with the same isotopes, e.g. oceanic basalts vs the depleted mantle (Mo et al., 2008; Niu, et al., 2013; Huang et al., 2014).

5.3.3. Re-evaluation of previous metamorphic interpretation

Zircons in the eclogites from the NQ-UHPM belt mostly give two age populations, one being interpreted as protolith age for the magmatic cores and the other as metamorphic ages recorded by zircon rims. Interpreting U/Pb ages with respect to the P-T-t of eclogites requires establishing whether the zircon was inherited from the protolith, formed during subduction metamorphism, or formed during exhumation (Baldwin et al., 2004). Zr contents in the bulk compositions of the mafic protolith in the Qilian Orogenic belt range from several ppm to 200 ppm, mostly <100 ppm (Song et al., 2003; Yang, et al., 2006; Zhang et al., 2008). Given the relatively Zr-poor bulk composition in these mafic protoliths, the interpretation of zircon growth from the protolithic magma might be problematic. For example, the Ky-eclogite from the Dulan area, the UHMP assemblage, spatially closest to the granitoids of this study possesses only 4.6 – 12.1 ppm Zr (Zhang et al., 2008). These Ky-eclogites are depleted in LREE and HREE with positive Sr and Eu anomalies, reflecting the troctolitic protolith of cumulative origin. Zircon gives ~516 Ma for the magmatic core and ~445 Ma for the metamorphic rim. These two ages were interpreted respectively as protolith age at a mid ocean ridge and UHP metamorphic age during subduction (Zhang et al., 2008). This interpretation may not be reasonable largely due to the very low Zr content in the bulk rock composition. Zircon saturation for basaltic composition melts is very high, up to thousands of ppm (Dickinson and Hess, 1982; Hanchar and Watson, 2003; Boehnke et al., 2013). According to the latest experiments on the zircon saturation in melts (Boehnke et al., 2013), the basaltic liquids require unrealistically high abundance of >5000 ppm Zr to directly crystallize zircon and the subsequent conclusion is that zircons found in mafic environments must have crystallized from late stage, evolved melts (Boehnke et al., 2013) or crustally contaminated melts (Zheng et al., 2006). 5000 ppm Zr may be

too much; hundreds of ppm might be sufficient to crystallize zircons based on observations in the literature (Visona et al., 2007). The magma parental to troctolite normally have average 60 ppm Zr based on the global data, too low to crystallize any zircon at the early cumulating stage. At this point, the magmatic cores in Ky-eclogites are melt-controlled but may not be crystallized at the mid-ocean ridge but grown during subduction or even collision duration.

5.3.4. Re-evaluation of the previous collision timing

Changes in isotopic compositions of magmatic rocks can be used successfully to trace the impact of the collision on the geochemistry of the igneous rocks (Elburg et al., 2005; Bouilhol et al., 2013). In this study, the Gcha rocks slightly predate the HY rocks (~450 Ma v.s. ~445 Ma, Fig. 5.3) and HY rocks have much more heterogeneous sources than Gcha (Table 5.6). The pronounced changes in the isotopic variations can be explained by the arrival of the leading edge of the Qaidam continental lithosphere beneath the overriding Qilian plate (Fig. 5.8). The large variation of zircon $\varepsilon_{Hf}(450)$ values in the range of the ~ -60 – 0 (Fig. 5.6B) indicate the anatexis of old crustal material and addition of the juvenile components. While their small negative whole rock ε_{Nd} and ε_{Hf} values (Table 5.3, Fig. 5.5A) suggest the prominent juvenile components in the magma sources. We note that the zircon age distributions in the metamorphic rocks (Fig.12 in Zhang et al., 2008, Fig.8 in Zhang et al., 2010) are very similar to those in our granitoids: indistinguishably varying from ~ 440 – 510 Ma (Fig. 5.2). Although zircon ages obtained from the granitoids cannot be grouped based on the zircon structures or the chemical compositions (zircon trace elements, Appendix G), zircon ages collected from the eclogites were subdivided into magmatic population and metamorphic population based on the contrast CL images (Zhang et al., 2008; Zhang et al., 2010). It is discussed above that some zircon core ages may not record the protolith formation age but the underthrusting process. It is possible that the magmatic core in the eclogite has the same origin as those in the granitoids. It is not easy to evaluate that the continuous age spread results from one long lasting event or multiple events due to the continuing replenishment of magmas. It is certain, however, that

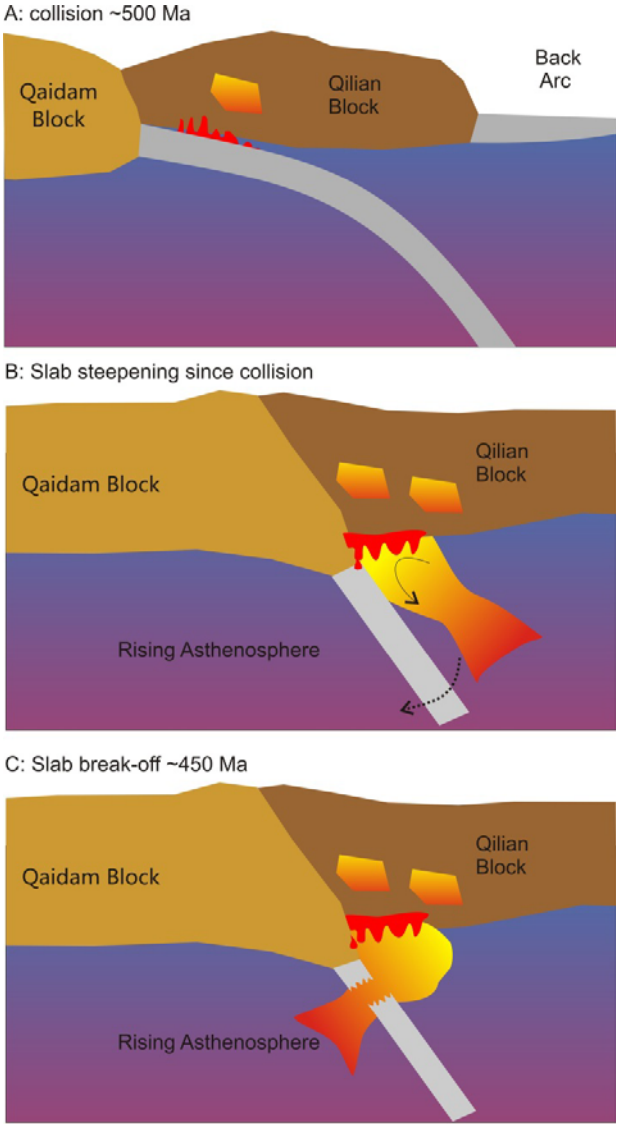

Fig. 5.8. A, Collision between the Qaidam Block and Qilian Block initiated at ~500 Ma and the syn-collisonal magmatism. B. the slab started steepening since collision and caused the enhanced mantle wedge convection producing magmatism. C, slab finally broke off at ~450 Ma. The uprising hot asthenosphere mantle caused the extensive magmatism at ~450 Ma.

the formation of these Gcha and HY granitoids is temporarily overlapping with the eclogite-facies metamorphism at ~450 Ma in the NQ-UHPM belt, suggesting a close relationship between the rapid exhumation of the ultrahigh-pressure metamorphic rocks and the contemporary Gcha and HY rocks. The association of exhumed high-pressure (HP) rocks with igneous rocks may be indicative of the slab break-off (Davies and von Blanckenburg, 1995; von Blanckenburg and Davies, 1995; Sun et al., 2002). The slab break-off would result in the uprising hot asthenosphere which may undergo

decompression melting and also provide sufficient heat to melt the overlying metasomatized mantle lithosphere and produce the basaltic magma to further partial melt the various crust materials. The derivative magma can have varying compositions, ranging from alkaline, ultrapotassic to calc-alkaline melts (Davies and von Blanckenburg, 1995). The calc-alkaline high-K to shoshonitic compositions of our granitoids probably result from partial melting of the hydrous, calc-alkaline to high-K calc-alkaline, mafic to intermediate crustal rocks (Roberts and Clemens, 1993) and possibly mixed with melts derived from the smallest degree melting of enriched layers in the overriding lithosphere (Davies and von Blanckenburg, 1995).

If the age population of ~450 – 460 Ma related to slab break-off, the collision should have happened normally ~ 20 – 25 Ma earlier (van Hunen and Allen, 2011) accompanying abundant magmatic events (Mo et al., 2008; Niu et al., 2013; Huang et al., 2014). The large scale of the magmatism prior to 470 Ma in the NQ-UHPM belt and QB is not yet extensively identified but the abundant magmatic zircon ages since ~510 Ma (Fig. 5.2, and Chapter 4) in the granitoids and metamorphic rocks (Zhang et al., 2008; Zhang, et al., 2010; Song et al., 2013) indicate the existence of magmatism at that time. In this case, the large age spread between 440 – 510 Ma could be explained. The magmatism was initiated since the collision at ~500 Ma. Once the collision started, the subducting oceanic slab started steepening under the gravity and result in the enhanced mantle corner flow which provides the heat to produce magmatism (Fig. 5.8). This is a gradational process until the slab finally detached. Therefore, the magmatism could possibly sustain for ~ 60 Ma until ultimate break-off. This model is also consistent with the metamorphic interpretation by Xu et al. (2006) who concluded according to the high-pressure metamorphic rocks that the exhumation began at 470 – 460 Ma.

The contemporary Gcha and HY granitoids in the Qilian Block were previously in Chapter 4 considered as the syn-collisional products at ~450 Ma and zircons older than 450 Ma had to be interpreted as xenocrysts which record the previous arc magmatism or oceanic crust formation

(Chapter 4). The old model is consistent with the tectonic evolution model built by Song et al. (2006; 2013). The new model is consistent with the tectonic frame suggested by Xu et al., (2006). Based on the current understanding, both of them are technically sound and both need more work to test.

Chapter 6: Mixing induced discrepancy between whole rock Hf isotopes and zircon in situ Hf isotopes

6.1. Introduction

Many efforts have been made to understand the continental crust growth during the past few decades, in which case, isotopic composition of zircons have been extensively applied. While using zircon Hf isotopes to discuss the magma processes, two important issues need to be carefully considered: (1) Do zircon Hf isotopes faithfully reveal the isotopic compositions of the magma? (2) How does continental crust achieve its characteristic bulk andesitic composition? Zircon can effectively preserve the initial $^{176}Hf/^{177}Hf$ ratios of an igneous host rock (Pettingill and Patchett, 1981; Kinny and Maas, 2003) due to its low Lu/Hf ratio. The Hf isotopic compositions of zircon can be utilized as a geochemical tracer of rocks' origin in the same way whole-rock Nd isotopes are used (Kinny and Maas, 2003) and zircon Hf isotope compositions have been used to trace rock origin and crust-mantle evolution (Kinny et al., 1991; Thirlwall and Walder, 1995; Amelin et al., 1999; Amelin et al., 2000; Griffin et al., 2000; Griffin et al., 2002; Kemp et al., 2007; Pietranik et al., 2013). However, in this paper, we demonstrate the big discrepancy between whole-rock and zircon Hf and we emphasize that zircon Hf isotope data must be used with caution.

Many models have been proposed to explain the continental crust growth including the standard 'island arc' model (Taylor and McLennan, 1985), 'mantle plume' model (Stein and Hofmann, 1994; Condie, 1998, 2000; Niu et al., 2003;) and 'continental collision zone' model (Niu et al., 2007, 2013; Mo et al., 2008; Niu and O'Hara, 2009; Huang et al., 2014; Chapter 4). It has been widely accepted that the continental crust has bulk andesitic composition (Taylor, 1967, 1977; Taylor and McLennan, 1985; Rudnick and Gao, 2003) which cannot be well explained by the standard continental crust growth model—"island-arc" model (Taylor and McLennan, 1985) because products in the island arc setting are basaltic rather than andesitic (Niu and O'Hara, 2009; Niu et al., 2013). To address this problem, the removal of mafic/ultramafic lower arc crust cumulate is strongly recommended (Kay and Mahlburg Kay, 1993; Rudnick, 1995; Plank, 2005). For example, amphibole-bearing mafic enclaves of cumulate origin in the arc have been highlighted to efficiently

drive the mafic magma towards the andestic compositions and provide geological evidence of the crustal differentiation models of arc magma (Hidalgo and Rooney, 2010). The Kekeli batholith in the North Qilian Orogenic belt (NQOB) contains ubiquitous amphibole-rich cumulates. Systematic investigation has never been done there before. In this study, we evaluate the sources and processes of Early Paleozoic Kekeli batholith by analysing major and trace element compositions, zircon in situ Hf and whole rock Sr-Nd-Pb-Hf isotopes of both mafic magmatic enclaves (MMEs) and host rocks in order to look into magma processes as well as the tectonic linkage to the surrounding tectonic units. We provide a consistent picture of magma interaction between isotopically diverse magmas and the induced discrepancy between whole rock Hf (WR-Hf) isotopes and zircon *in situ* Hf (Zir-Hf) isotopes.

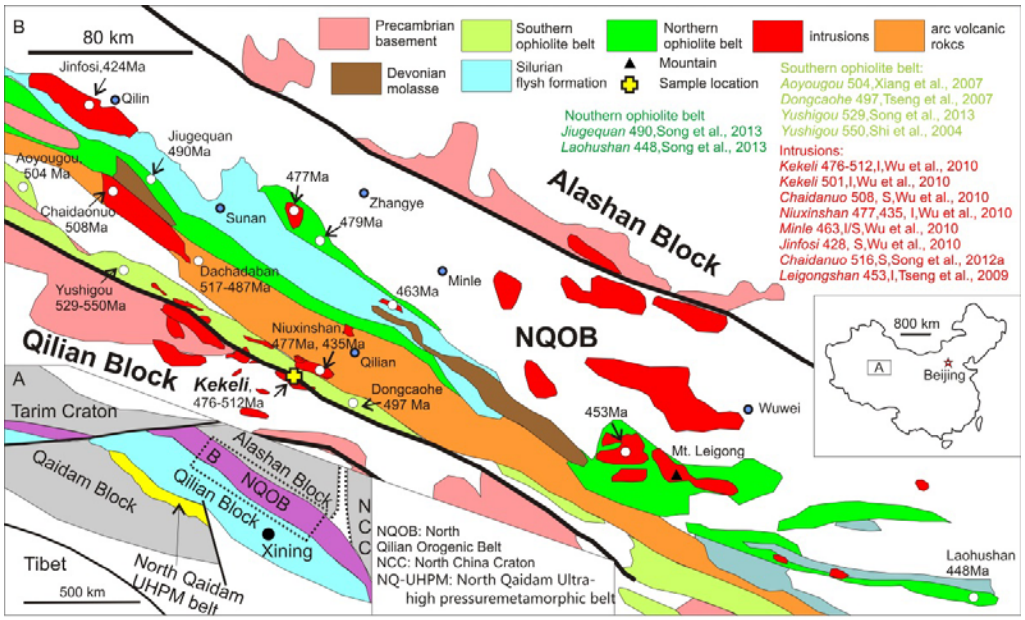

Fig. 6.1. A, Schematic map showing major tectonic units of the Qilian Orogenic Belt (after Song et al., 2013). B, Simplified geological map of the North Qilian Orogenic Belt (NQOB) showing the distribution of granitoids and ophiolites (after Song et al., 2013). Data compilation for granitoid intrusions is from Huang et al. (2013b), and for ophiolites is from Song et al., (2013). Fig. 6.2. Photomicrographs under plane polarized light and SiO_2-variation diagrams showing the correlations among samples. QL10-22: cumulate texture. QL10-21: heteradcumulate texture. QL10-26: Secondary Amp and Bi rims on the pyroxene. QL10-14: granitic group 1 contains Bi without Amp. QL10-23: group 2 with intermediate composition containing Amp. (Amp: amphibole, Pl: plagioclase, Q: quartze, Ep: epidote, Opx: othorpyroxene, Cpx: clinopyroxene, Bi: biotite, Kfs: K-feldspar, ilm: ilmenite. MME: mafic magmatic enclave).

6.2. Tectonic setting and geologic background

The North Qilian Orogenic belt (NQOB), Qilian Block (QB) and North Qaidam ultrahigh pressure metamorphic belt (NQ-UHPM) are three major tectonic units of the Qilian-Qaidam system on the northernmost margin of the Tibetan Plateau (Fig. 6.1 A, B).

We collected 10 samples including 5 mafic magmatic enclaves (MMEs) from the Kekeli batholith in the NQOB (Table 6.1). The Kekeli batholith is located on the southern margin of the NQOB (Fig. 6.1B) intruding the Precambriam meta-volcanic rocks, pelitic rocks and clastic rocks within the southern ophiolite belt. This batholith is mostly diorite-granodiorite in composition with a few plagiogranites (Wu et al., 2010). It is characterised by the presence of a large amount of MMEs. Wu et al. (2010) report one granodiorite of 501 Ma and one plagiogranite of 512 Ma from Kekeli Batholith. They suggest that the granodiorite was derived from subducted oceanic crust while the plagiogranite was produced by partial melting of gabbro based on age and petrology.

6.3. Samples

The Kekeli batholith contains abundant enclaves with size up to 1.5 m in diameter. The contacts between MMEs and host rocks are gradational, indicating supersolidus condition. Mineralogy for all the samples is listed in Table 6.1 and described below. Mineral modes are determined by point counting.

The gabbronorite enclave QL10-26 contains abundant orthopyroxene (Opx), clinopyroxene (Cpx) and ilmenite (Ilm) (Table 6.1, Fig. 6.2). Opaque Ilm makes up to 5% of the sample which is consistent with its cumulate origin. Hydrous minerals Amphibole (Amp) and biotite (Bt) appear as rims of pyroxene (Px) (Fig. 6.2), suggesting that P-T conditions or compositions had changed with time. Plagioclase (Pl), quartz (Qtz) and K-feldspar (Kfs), plus accessory minerals such as apatite and zircon are also present. The contacts between QL10-26 and host rocks are gradational and Px (both Opx and Cpx) decreases from QL10-26 towards the host.

MMEs are mafic diorite, containing dominantly Amp and Pl (Fig. 6.2). Various Qtz and Kfs are present as interstitial phases. Alteration phases include epidote (Ep) after Amp, chlorite (Chl) after biotite and clay minerals after feldspar. Some epidotes also present as the primary euhedral phase. The advanced hydrothermal alteration of the sample is obvious (actinolite in QL10-25, QL10-27). Some MME display a heteradcumulate texture (QL10-21, Fig. 6.2) where poikilitic amphibole encloses mostly plagioclase which is regarded as imperfect fractional crystallization (Claeson and Meurer, 2004; Larocque and Canil, 2010). The host rocks can be divided into two groups based on their mineralogy and field observations. Group 1 (granite QL10-14/15) is granitic, bearing biotite with no Amp and do not contain MMEs (Fig. 6.2). Group 2 (Diorite QL10-23/24/27) is intermediate in composition, containing Amp and hosting MMEs (Fig. 6.2).

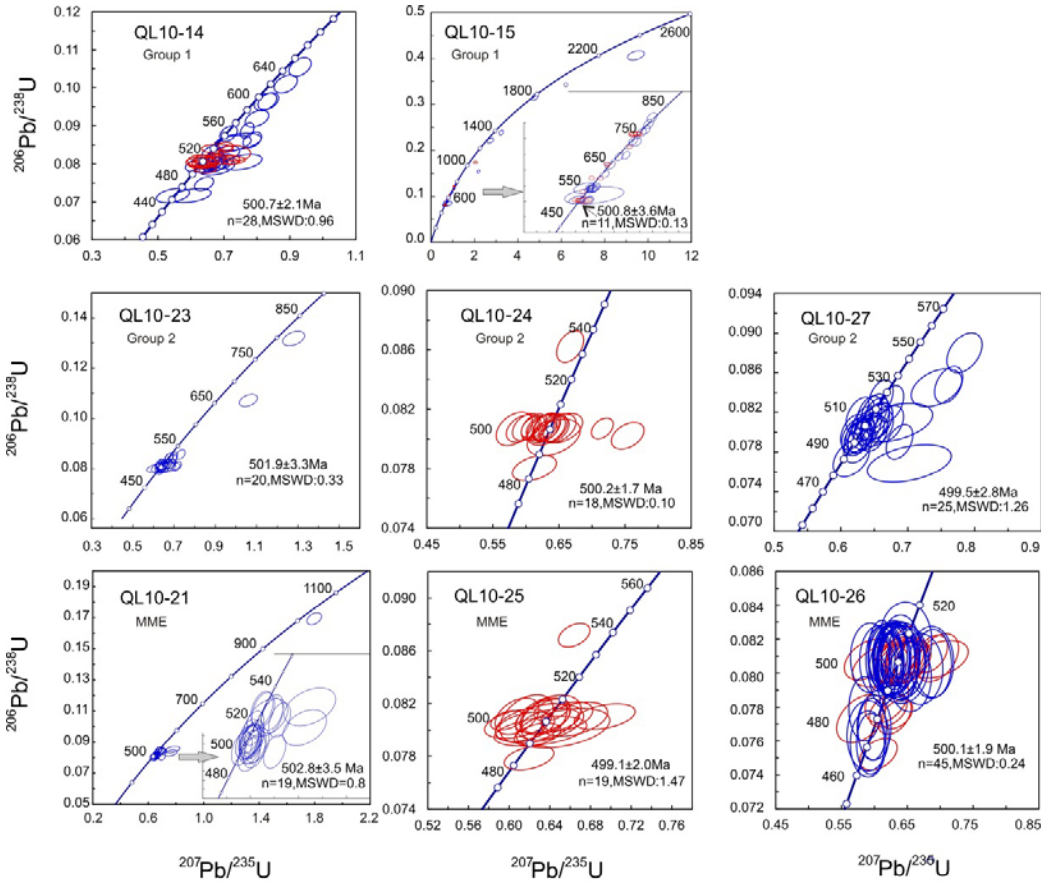

Fig. 6.3. Zircon U-Pb Concordia diagrams to show host rocks and MMEs have the same crystalline age of ~ 500 Ma.

6.4. Sample preparation and analytical techniques

All the samples were analysed for bulk-rock major and trace element. Eight zircon U-Pb dated samples were analysed for bulk-rock Sr-Nd-Pb-Hf isotopes. Zircon in situ U-Pb dating was conducted in both Wuhan (red color, Fig. 6.3) and Beijing (blue color, Fig. 6.3). In situ zircon Hf isotope analysis were determined at the same spot as U-Pb dating.

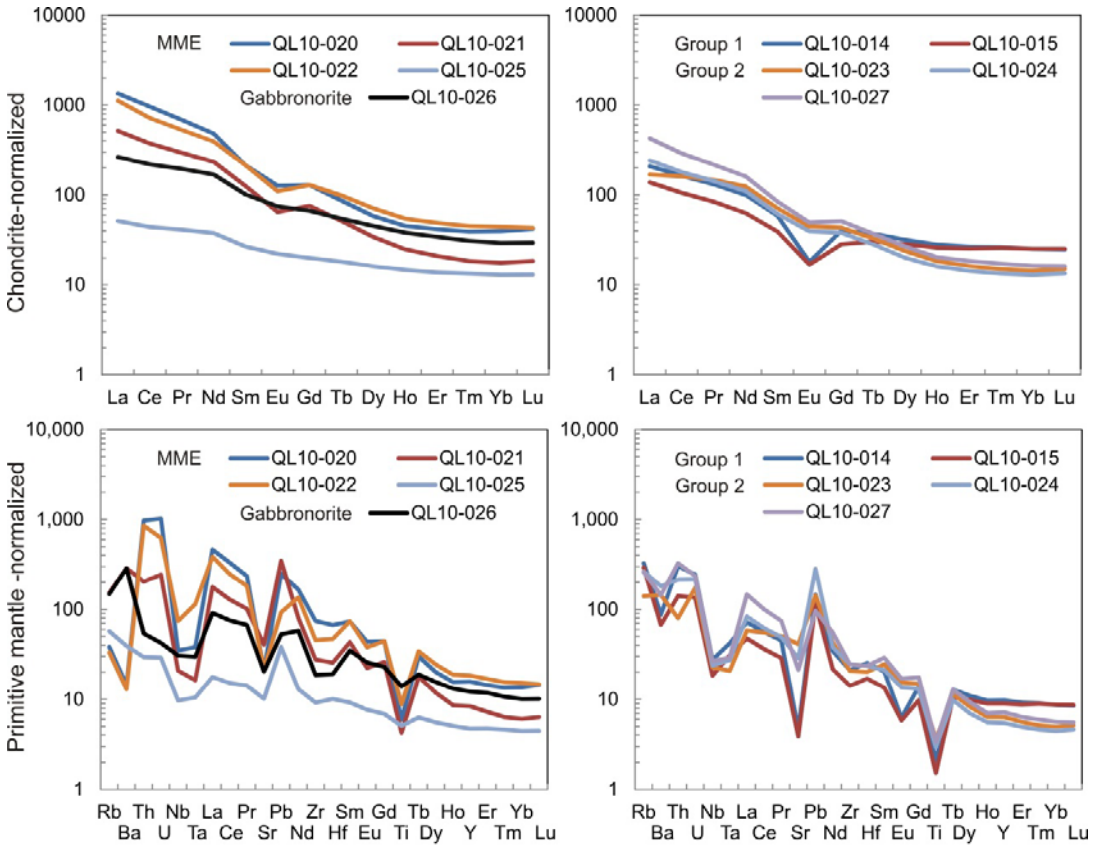

Fig. 6.4. Chondrite-normalized rare earth element patterns and primitive mantle-normalized diagrams (Sun and McDonough, 1989). QL10-26 has no Eu anomaly and displays the fairly flat LREE pattern; Group 1 has a largest negative Eu anomaly. Group 2 and other MMEs have the intermediate negative Eu anomalies

6.5. Results

6.5.1. Major and trace elements

Major and trace elements are given in Table 6.2. All of them define good linear trends on the Harker diagrams (Fig. 6.2). Gabbronorite QL10-26 has less enriched light rare earth elements (LREEs), no Eu anomaly, and small Pb and Ti anomalies (Fig. 6.4). Group1 rocks have biggest Eu, Pb and Ti anomalies. MMEs generally display smaller Eu, Pb and Ti anomalies than host rocks on the rare earth element (REE) patterns and spider diagrams (Fig. 6.4). Group 1 rocks show similar trace element pattern (Fig. 6.4). Group 2 rocks resemble bulk continental crust characters (Fig. 6.4), e.g. negative Nb-Ta-Ti anomalies, positive Pb anomalies and small negative Eu anomaly.

6.5.2. Zircon geochronology and geochemistry

Eight samples were analysed for zircon in situ U-Pb dating and in situ Hf isotopes (Table 6.3, 6.4 respectively). U-Pb Concordia plots are shown in Fig. 6.3. Zircon trace element data are given in Appendix H. Fig. 6.5 reveals multiple zircon populations and complex internal structures. In group 1, QL10-14 and QL10-15 contain abundant zircons displaying chaotic zoning, reflecting the post-magmatic modifications e.g. metamictisation (Fig. 6.5). The magmatic zircons have coherent concordant ages of ~ 500 Ma. The inherited zircons have ages as old as >2.0 Ga, indicating the involvement of old crust. The younger inherited zircons have ages spread out from 550 ~ 800 Ma (Fig. 6.3) on or close to the Concordia. All the other samples have the same coherent crystalline age of ~ 500 Ma. Generally, the QL10-26 has zircon fragmented with strip zoning typical in the mafic rocks and some grains with chaotic zoning; The Group 1 samples have abundant zircons with both chaotic zoning and magmatic zoning; Group 2 and other MMEs contain zircons types both seen in QL10-26 and Group 1. Details are described below.

Group 1

Zircons in granite QL10-14 mostly have core-mantle texture with metamorphic cores and magmatic rims (Fig. 6.5). Magmatic parts were carefully analysed to constrain the crystallization age (Fig. 6.4). Considering the results from both Beijing and Wuhan (red and blue color in Fig. 6.4), apparent $^{206}Pb/^{238}U$ age is 500.7 ± 2.1 Ma.

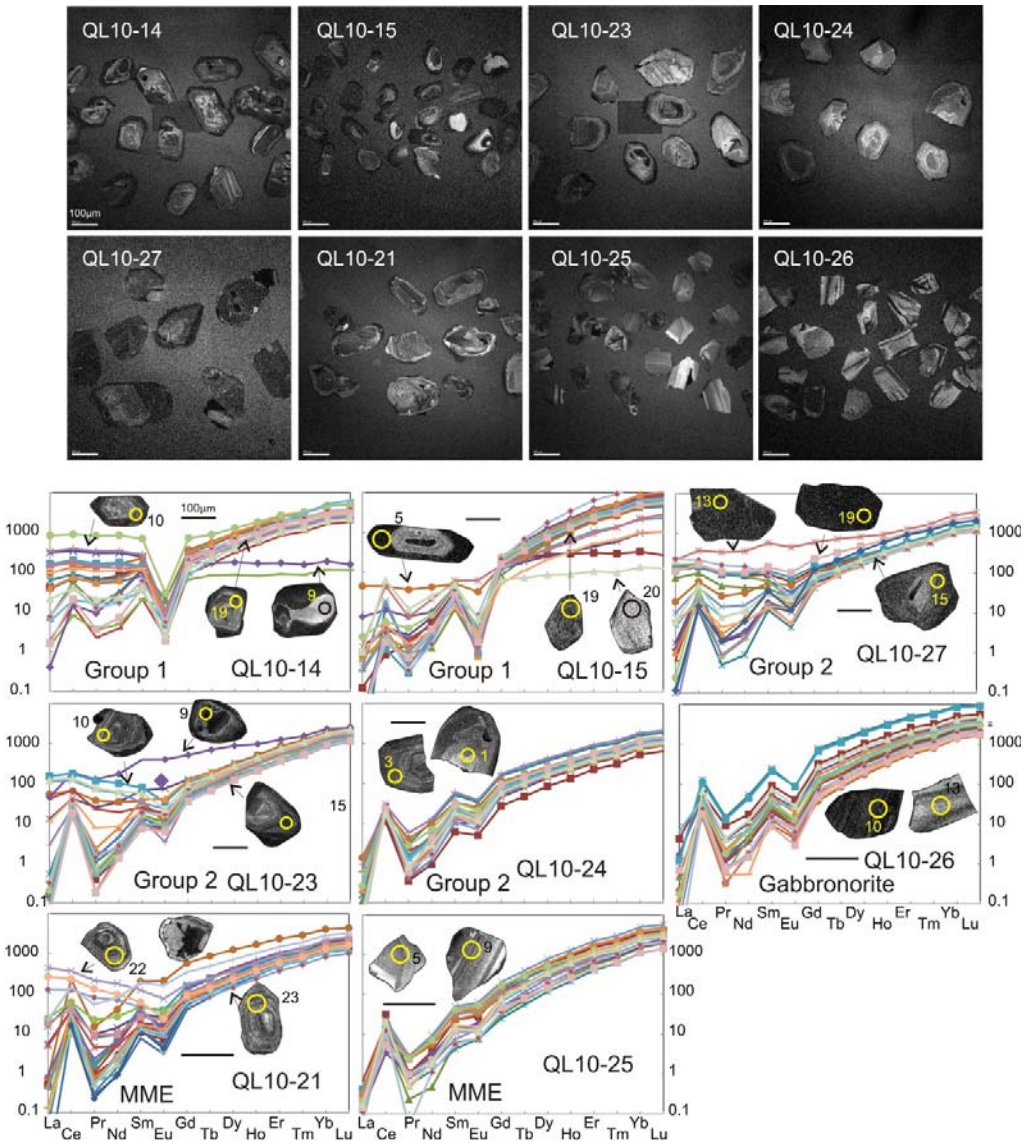

Fig. 6.5. Zircon cathodoluminescence photos and trace elements.

QL10-15 has metamorphic and magmatic grains (Fig. 6.5), showing various internal structure, including oscillatory zoning, homogenous, core-mantle-rim texture, planar banding, patchy, fir-tree or radial sector zoning, reflecting a rather complex history. In situ dating was carried on magmatic grains, and gives apparent $^{206}Pb/^{238}U$ ages of 502.4 ± 4.0 Ma.

Group 2

Diorite QL10-23/24/27 contains more magmatic grains. The zircons with non-magmatic texture are similar to those in QL10-14/15 (Fig. 6.5). Magmatic zircons are mostly homogenous, fir-tree, patchy or sector zoning. Age is constrained as ~ 500 Ma (Fig. 6.3).

MMEs and Gabbronorite

QL10-21 has abundant zircons with chaotic zoning which are common in Group 1 and most of them reveal complex chaotic zoning (Fig. 6.5). We carefully analysed the oscillatory magmatic grains and have $^{206}Pb/^{238}U$ age is 502.8 ± 3.5 Ma, which represents the crystallization age. Zircons in QL10-25/26 are mostly fragments, homogenous or have strip bands (Fig. 6.5). The presence of the zircons with non-magmatic zoning similar to those in QL10-21 indicates their genetic relationship. $^{206}Pb/^{238}U$ ages are ~ 500 Ma.

Majority of zircons display the typical REE pattern (Fig. 6.5), e.g. a steeply-rising slope from LREE to the HREE with a positive Ce-anomaly and negative Eu-anomaly, indicating the original igneous origin. QL10-25 possesses the smallest Eu anomaly, consistent with its small Eu anomaly in the

whole-rock REE pattern (Fig. 6.4). The grains with high LREE abundances probably result from the contamination of apatite inclusions. Some metamorphic grains in Group 1 have flat HREE patterns (Fig. 6.5) probably due to the equilibrium with the minerals rich in HREEs, i.e., garnet (Rubatto, 2002). The dating results indicate that both MME and host rocks crystallized almost simultaneously at ~ 500 Ma.

6.5.3. Whole rock Sr-Nd-Pb-Hf isotopes and zircon in situ Hf isotopes

Whole rock Sr-Nd-Pb-Hf isotopic data for MMEs and host rocks are given in Table 6.5. $I_{Sr,}$ $Pb_{(i),}$ $\varepsilon_{Nd}(t)$ and $\varepsilon_{Hf}(t)$ refer to the age corrected values, whereas ε_{Nd} and ε_{Hf} refer to the present-day values. Group 1 host rocks have lower $\varepsilon_{Nd}(t)$ (-6.05 – -6.70) (Fig. 6.6A) and relatively highly radiogenic I_{Sr} (Fig. 6.6C-D). MMEs have rather limited variation in $\varepsilon_{Nd}(t)$ values (-1.88 – 0.54) (Fig. 6.6A),

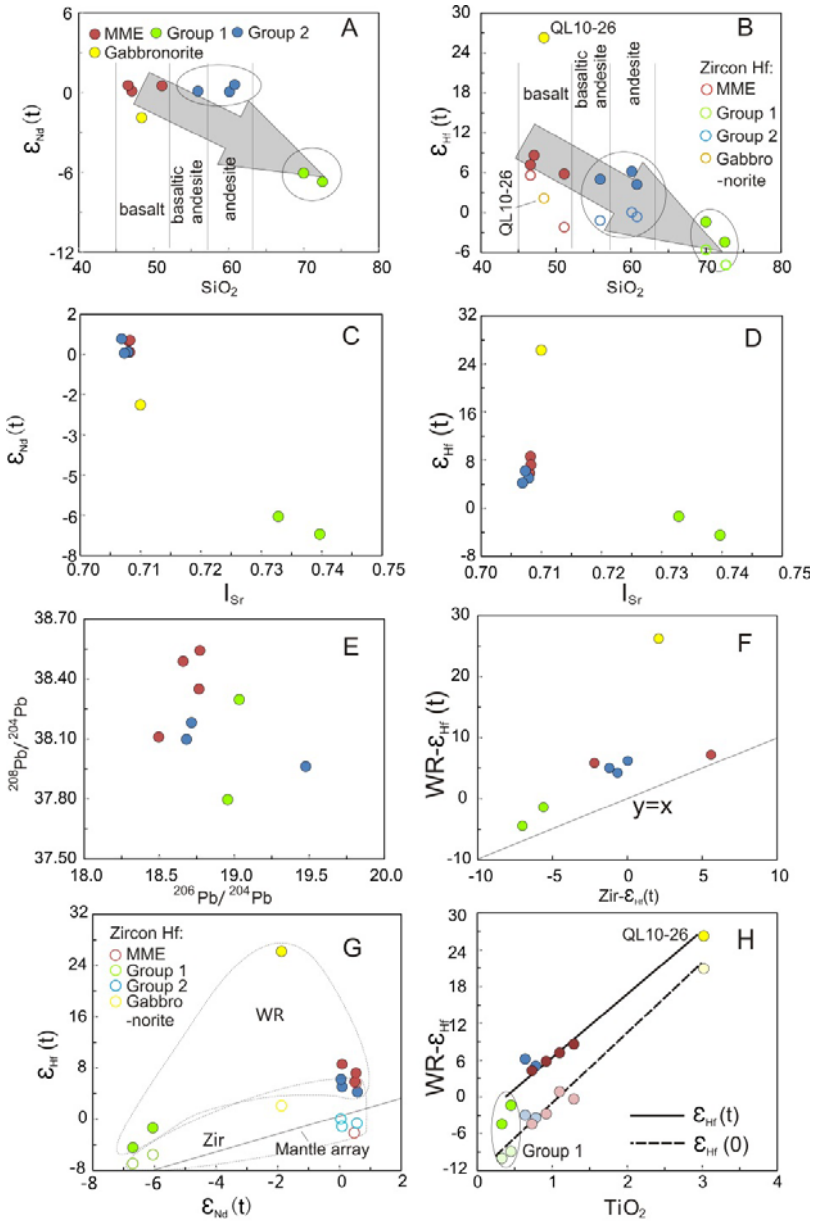

Fig. 6.6. A, Age corrected bulk-rock Nd isotopes vs SiO_2 to show a broad negative correlation. Group 1 samples have lowest $\varepsilon_{Nd}(t)$. Group 2 samples have intermediate isotope composition between two endmembers. B, Age corrected bulk-rock Hf isotopes vs. SiO_2 to show the broad negative correlation. Group 1 samples have lowest $\varepsilon_{Hf}(t)$. Group 2 samples have the intermediate isotope composition between two endmembers. Zircon in situ Hf (Zir-Hf) data (open symbols) are also plotted for comparison. C, negative correlation between Nd and Sr isotopes. D, negative correlation between Hf and Sr isotopes. E, scatter Pb isotope plot showing between-sample heterogeneity. F, comparison between Zir-Hf and WR-Hf to show the discrepancy between the two. G, Zir-Hf (open symbols) and WR-Hf plot against Nd isotope showing the discrepancy between Zir-Hf and WR-Hf and decoupling between WR-Hf and Nd isotope. H, Correlations between age corrected /non-corrected WR-Hf and TiO_2.

overlapping with the range of Group 2 host rocks ($\varepsilon_{Nd}(t)$= 0.05 – 0.59) (Fig. 6.6A) but large variation in $\varepsilon_{Hf}(t)$ (Fig. 6.6B). The scattering on the plot of $^{208}Pb/^{204}Pb_i$ and $^{206}Pb/^{204}Pb_i$ (Fig. 6.6E) indicates the heterogeneity in Pb isotopes.

For samples QL10-14 and QL10-15, we preferentially analysed the magmatic grains along with only a few inherited zircons (QL10-15, Table 6.3). Therefore, these zircon *in situ* Hf isotopes mostly reflect the latest magma composition with a little inheritance. The *in situ* Hf isotopes show very limited variations within each sample (Table. 6.4) indicating the relatively homogenous composition of the magma from which zircons crystallized. A few inherited zircons in granite QL10-15 were also analysed and show the negative ε_{Hf} (500) of -20 (Table. 6.4). Traditionally, zircon *in situ* Hf (Zir-Hf) isotopes is considered to faithfully record the magma isotopes at the time of crystallization (Kinny and Maas, 2003) and whole rock Hf (WR-Hf) isotopes should agree well with Hf composition in constituent zircons (Schmitz et al., 2004). However, in our study, the zircon $\varepsilon_{Hf}(t)$ is dominantly <0 inconsistent with the dominant whole-rock with ε_{Hf} >0 (Fig. 6.6B). The discrepancy between WR- Hf and Zir-Hf isotopes is so significant (Fig. 6.6F-G) that demonstrate the (1) Zir-Hf isotopes do not represent the WR Hf isotopes; (2) zircon is not the only major host of Hf. One may argue that, if not considering the outlier QL10-26 on Fig. 6.6F-G, WR-Hf is not significantly decoupled from Nd isotope. The important observation here is that the WR-Hf isotope is well correlated with TiO_2 (Fig. 6.6H) which suggests that the apparent 'outlier' QL10-26 in Fig. 6.6 is actually a systematic result rather than an accidental outlier. Therefore, the decoupling between WR-Hf and Nd isotopes is real and significant.

6.6. The discrepancy between in situ zircon Hf and whole rock Hf isotopes

There is significant discrepancy between WR-Hf and Zir-Hf isotopes and decoupling between WR-Hf and Nd isotopes (Fig. 6.6G). This discrepancy cannot be explained by 'analytical bias' (i.e., the inherited cores are analysed in the whole rock but not analysed in *in situ* zircons) because the inherited cores have much more negative $\varepsilon_{Hf}(t)$ (see those in QL10-15, Table 6.4), dissolving them

should result in the lower WR $\varepsilon_{Hf}(t)$s rather than the much higher WR $\varepsilon_{Hf}(t)$ than Zircon $\varepsilon_{Hf}(t)$. This demonstrates that non-zircon phases host the abundant radiogenic Hf in the rocks. To understand the decoupling and discrepancy, the correlation between WR-Hf and TiO_2 may offer some clues (Fig. 6.6H).

Previous studies (Heinonen et al., 2010; Pankhurst et al.2013) have reported the positive correlation though broad correlation between initial Hf isotope ratio and Ti contents in zircons and interpret it to result from increasing crustal assimilation-related cooling. In our samples, there is no correlation between zircon Hf isotopes and zircon Ti contents (Fig. 6.7A), which means that crustal assimilation, if any, is not related to Ti contents in zircons nor with magma cooling. The tight (vs. broad) correlation on Fig. 6.6H, therefore can be explained in an alternative way: Ti-rich minerals are the important high $\varepsilon_{Hf}(t)$ host. This could happen in two scenarios: (1) Ti-rich minerals produce the high $\varepsilon_{Hf}(t)$ in the comparable way of 'garnet effect'; (2) high TiO_2 and radiogenic Hf isotope are different products in response to a common process.

6.6.1. Ti-rich minerals— important Hf host

In our samples, average Hf contents in zircons increase as the whole rock SiO_2 increases (Fig. 6.7B). This could be explained by the preference of Zr over Hf in the early-formed zircons (Wooden et al., 2007). At the same time, the WR Hf concentrations remain almost the same throughout cumulates to the host rocks (Fig. 6.7B). Therefore, more proportions of Hf reside in zircons in the felsic lithologies than those in the mafic lithologies because mafic lithologies have (1) lower Hf concentration in zircons (Fig. 6.7B); (2) lower zircon modes (zirconium undersaturation in the mafic magma see below). Simple binary mixing calculation (Table. 6.6) is done to estimate how much Hf resides in the non-zircon phases and how radiogenic they are (Fig. 6.7D). Results show that > 40% Hf in the whole rock Hf hosted by non-zircon phases and they are much more radiogenic than those in the zircons (minimum estimates, see Table. 6.6). Note that, calculation of

Hf isotopes in the non-zircon phases is not involved with Ti contents at any stage, but the results show that the Hf isotopes in the non-zircon phases is positively correlated to whole rock TiO_2 (Fig. 6.7D).

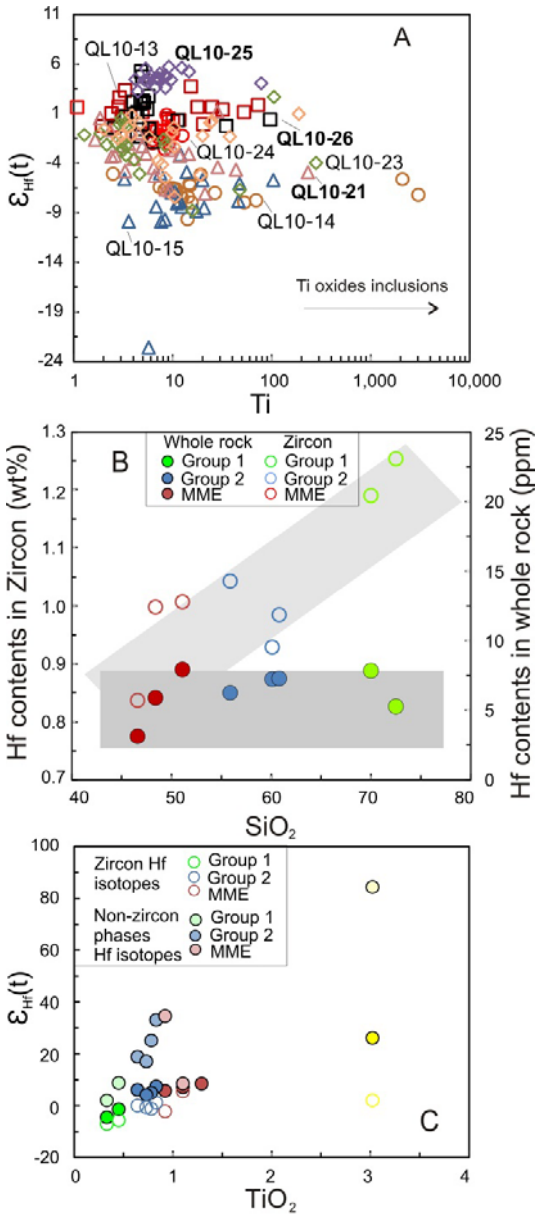

Fig. 6.7. A, Zircon in situ Hf isotopic composition plot against zircon Ti contents showing no correlation between the two. B, Zircon Hf contents and whole rock Hf contents plot against SiO_2 showing that (1) the whole rock Hf concentration remains more or less the same throughout; (2) Hf concentration in zircon increases from mafic to felsic. C, comparison of whole rock, zircon and non-zircon phases Hf isotopes.

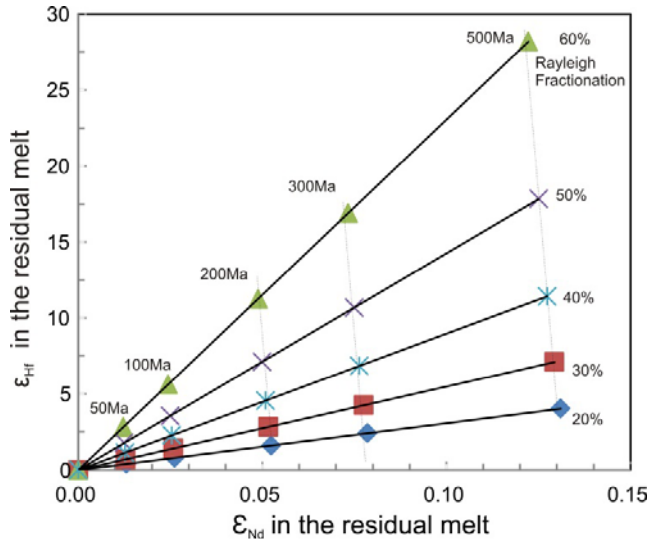

Fig. 6.8. Model time-integrated modern isotopic compositions in the residual magma for removal of up to 60% of pure ilmenite. Rayleigh fractionation equations are used. For clarification, we start with andesitic elemental composition (data from Niu and O'Hara (2009)) with chondritic isotopes. Results showing the huge in-growth of ε_{Hf} with negligible changes in ε_{Nd}. However, to achieve the 26 units shift in ε_{Hf} from the mantle array (ε_{Hf}=1.33* ε_{Nd}+3.19, (Vervoort and Blichert-Toft, 1999)) in QL10-26, up to 60% of pure ilmenite and 500 myrs integration is required. Fractionation of 60% pure ilmenite means original magma should contain at least 30 wt% TiO_2 (ilmenite has 50% TiO_2) and experience 600% (6 times of its own volume) fractionation if there is up to 10% ilmenite in the fractionated assemblages. Importantly, 500 myrs integration is too long to be realistic for any fractionation process within the magma chamber. Therefore, ilmenite fractionation cannot explain the radiogenic Hf in our samples despite its great potential.

6.6.2. Can Ti-rich minerals cause the decoupling in initial Nd-Hf isotopes?

Fe-Ti oxides have been proposed to explain the decoupling of Nd-Hf isotopes in the granulite lower crust (Schmitz et al., 2004) despite the lack of direct data support. The correlation of WR-Hf ~ TiO_2 (Fig. 6.6H) in this study seems to support this hypothesis, especially sample QL10-26 which has the biggest decoupling/discrepancy (Fig. 6.6G, 6.7C), highest TiO_2 (Table 6.2, Fig. 6.6H), and most abundant ilmenite (Table. 6.1, Fig. 6.2). Ilmenite has extremely low $^{176}Lu/^{177}Hf$ (<0.0001, see the mineral separate data in Nowell et al. (2004)) due to different partitioning coefficients of Lu and Hf (Kd_{Hf}=1.39 vs. Kd_{Lu}=0.029, see compilation of Niu and O'Hara, (2009)), thus the crystallization of ilmenite results in extreme fractionation of Lu/Hf between ilmenite and any other co-precipitating phases. Similar to zircon, ilmenite would preserve its initial Hf isotopic ratios at the time of

fractionation while the equilibrating residual magma would evolve to very radiogenic Hf over time. At the same time, Sm and Nd are almost equally incompatible in ilmenite (Kd_{Sm}=0.009, Kd_{Nd}=0.008, Niu and O'Hara, 2009). Therefore, ilmenite may have potential to cause Nd-Hf isotopes decoupling as other minerals do, e.g., perovskite (Salters and Hart, 1991). Because our decoupling resides in the initial Nd and Hf isotopes rather than the present day values, it implies a long time interval between the early ilmenite fractionation and the final remaining magma solidification, in which case the remaining melt can develop decoupled Nd-Hf isotopic compositions from its original un-decoupling point. The simple modelling Fig. 6.8 (see figure caption for calculation) shows that fractionation of ilmenite make the remaining melt have huge in-growth of ε_{Hf} with negligible changes in ε_{Nd} if allowing hundreds of millions of years' integration. However, expecting the Nd-Hf isotopes decoupling in the initial values in our samples, it requires 500 myrs of time interval between early fractionation and solidification of the equilibrating magma in the magma chamber where 10-20 million years is the maximum. Therefore, ilmenite fractionation, although common in the mafic or felsic magma evolution, may cause the present-day Nd-Hf decoupling (Schmitz et al., 2004) but is not the reason of the initial Nd-Hf isotopes decoupling in our samples. Neither do other TiO_2 rich minerals (e.g. Amp, Bt) (similar modelling not shown). Extremely high $^{176}Hf/^{177}Hf$ has been reported in Cpx which is the major Hf host in the mantle (Salters and Zindler, 1995) and might be explained by the metasomatism or the ancient melt depletion and recent enrichment. But this interpretation has nothing to do with the fractionation process in the magma chamber as discussed here. In terms of fractional crystallization, due to the very low Hf and Ti concentrations in pyroxene compared to other Ti-rich minerals, Cpx is less likely the cause.

As demonstrated above, the decoupling is not produced by the fractional crystallization in the magma chamber. However, why $\varepsilon_{Hf}(t)$ is correlated with TiO_2 ? Is this correlation related to the discrepancy between WR-Hf isotopes and Zir-Hf isotopes?

6.6.3. Mixing—magma endmembers

The significant positive correlation between $\varepsilon_{Hf}(t)$ and TiO_2, combined with the broad negative correlations between both $\varepsilon_{Hf}(t)$ and $\varepsilon_{Nd}(t)$ and SiO_2 (Fig. 6.6A-B), is best explained by mixing processes. We consider QL10-26 is not early cumulated from a granitoid magma as other charnockites (Frost et al., 2000) but a hybrid of mafic lithologies and felsic melts. First of all, QL10-26 displays more depleted characters, i.e. 48 wt% silica (Table 6.2, 27 vol% Px (Table 6.1), 5 vol% Fe-Ti oxides (Table 6.1), small Pb and Ti anomalies, and no Eu anomaly (Fig. 6.4). Besides, charnockites are high temperature granitoids (>900 °C) (Kilpatrick and Ellis, 1992), however, Zr-in-whole rock temperature for QL10-26 is only 679 °C and Ti-in-zircon temperature is 715 °C (Table 6.5). Importantly, QL10-26 has the most depleted WR Hf isotopes ($\varepsilon_{Hf}(t)$=26), indicating it crystallized from a depleted source. Most likely, Px and Ilm are products from a basaltic composition, while, Qz, Pl and Kfs are the late-stage minerals from a more felsic composition (see below) and Amp rims on the Px probably record the interaction of these two magmas (see below). QL10-26 has TiO_2 up to 3.02%, significant higher than the normal mafic rocks with similar silica contents. However, Fe-Ti rich melts are natural consequences with relatively low liquidus temperature (1080-1100 °C) (Dick et al., 2000; Niu et al., 2002) during cooling and fractional crystallization of MORB evolution (Clague et al., 1981; Dick et al., 2000; Niu et al., 2002). Probably, QL10-26 crystallized from evolved Fe-Ti rich basalt.

The most felsic rocks QL10-14/15 are peraluminous (A/CNK >1.1), have the highest silica (70 wt %), lowest TiO_2, radiogenic I_{Sr} and negative $\varepsilon_{Hf}(t)$ and $\varepsilon_{Nd}(t)$ (Fig. 6.6C-D), and therefore represent an endmember close to crustal composition. The zircons have flat HREEs (Fig. 6.5) indicating the equilibrium with garnet pointing to mid-lower crust level. Other samples with intermediate composition between these two endmembers also have the intermediate isotopic compositions in between (Fig. 6.6A-B, especially on Fig. 6.6H). All these observations suggest a mixing process.

6.6.4. Mixing induced discrepancy between WR-Hf and Zir-Hf isotopes

The significant positive correlation between $\varepsilon_{Hf}(t)$ and TiO_2 could be the coherent results corresponding to mixing process, i.e., different minerals crystallizing at different stages. According to the experiments on the zircon saturation in melts (Boehnke et al., 2013), the basaltic liquids require >5000 ppm Zr to directly crystallize zircon. Zircons found in mafic environments must have crystallized from late stage, evolved melts (Boehnke et al., 2013) or crustally contaminated melts (Zheng et al., 2006). Therefore, 209 ppm Zr in QL10-26 is obviously undersaturated. Probably the pyroxene and ilmenite crystallized earlier at higher temperature when the zircon failed to crystallize due to the undersaturation. In this situation, the discrepancy between WR-Hf and Zir-Hf, therefore, can be explained. When the mantle-derived magma interacts with the crustal material, the possible scenario is that Ti-rich minerals, e.g. Amp, Fe-Ti oxides, and Bt, etc., crystallize from the more mafic composition at the relatively earlier stage of mixing and preserve the isotope signature closer to the mafic endmember. Zircons do not crystallize until the later stage when the hybrid magma is saturated in Zr. This is supported by the Ti-in-zircon thermometry. For example, the Ti-in-zircon thermometry for QL10-26 is only 715 °C (Zr-in-whole rock thermometry is even lower 679 °C) (Table. 6.5). This temperature is significantly lower than the crystallization temperature for pyroxene (> 1000 °C), amphibole (>850 °C) and biotite (> 750 °C) but within the range of felsic minerals (plagioclase, k-feldspar and quartz) crystallization temperature (< 750 °C) (Bogaerts et al., 2006). This means that the mafic minerals already crystallized significantly before the crystallization of zircons. Therefore, zircons generally record isotope compositions closer to the felsic endmember. TiO_2 decreases with increasing SiO_2, implying the fewer modes of Ti-rich minerals in the more felsic rocks, hence, the smaller discrepancy between WR-Hf and Zir-Hf (Fig. 6.6F). The MME sample QL10-25 has high TiO_2 but smaller discrepancy (almost identical WR-Hf and Zir-Hf) (Fig. 6.6F). This could be explained by the alteration/metamorphic process. Almost all the amphiboles in QL10-25 that have altered into actinolite, and ilmenite is rare, indicating a fluid-

presence environment. We failed to evaluate the ability of actinolite to host Hf during metamorphism. But studies have shown that Hf can be mobile (Woodhead et al., 2001) due to the fluids while the zircon-Hf isotopes are resistant to metamorphism (Kinny and Maas, 2003). When the amphiboles which are the major Hf host apart from zircons in QL10-25 were transformed to actinolite, they probably lost their own Hf isotopes. Meanwhile, zircons are resistant and preserved their Hf isotopes. Therefore, the WR-Hf is very similar to Zir-Hf. The group 1 granitic samples have slightly higher Ti-in-zircon thermometer temperature, reflecting the higher zircon saturation thus crystallize earlier/higher temperature. But these zircons almost entirely crystallized from the felsic magma which had little contribution from the mafic magma, thus, recorded the felsic endmember and has smaller discrepancy between the WR-Hf and Zir-Hf. Note that WR-Hf isotope is decoupled from Nd isotope but Zir-Hf is not (Fig. 6.6G), which indicate that the decoupling is inherited from the mantle not the crustal melt.

As discussed above, we aim to bring cautions in interpreting the zircon *in situ* Hf isotopes, specifically when mixing two isotopically different magmas where WR-Hf analysis or Hf isotope on the Ti-rich minerals is strongly recommended.

6.7. Magma chamber evolution—mixing associated with crystal fractionation

We consider the QL10-26 as a mixture between mafic lithologies and felsic melts. The presence of pyroxene in the magmatic charnockites has been considered as the indication of 'dry' magma; Frost et al. (2000) especially pointed out that pyroxene-bearing charnockites can form in any rock type if the water activity is low enough. And the derivative product is very similar to QL10-26 in terms of mineral assemblage. It has to be pointed out that the pyroxene in QL10-26 did not crystallize from the granitic magma but from the precursor basaltic magma.

Importantly, however, the water-saturated experiments on basaltic andesites/andesites suggest that the pyroxene can be the liquidus phases in the hydrous magma at the middle-lower crust level when

the temperature is higher (>950°C) compared to the Amp (850°C) (Grove et al., 2003; Bogaerts et al., 2006; Krawczynski et al., 2012). These experiments also have shown that the crystallization of amphibole is restricted to H_2O rich system (Grove et al., 2003; Bogaerts et al., 2006; Müntener and Ulmer, 2006). The secondary Amp rims on the pyroxene and biotite reflect the decreasing of temperature, e.g., from > 950 °C to 850°C rather than the water contents in the magma, e.g., from anhydrous to hydrous compositions. The presence of pyroxene alongside abundant Fe-Ti oxides in QL10-26 simply indicates a higher crystallization temperature in a hydrous system, probably at deeper level. This interpretation is consistent with the convergent tectonic setting of Kekeli batholith where fluxes of fluids are very high.

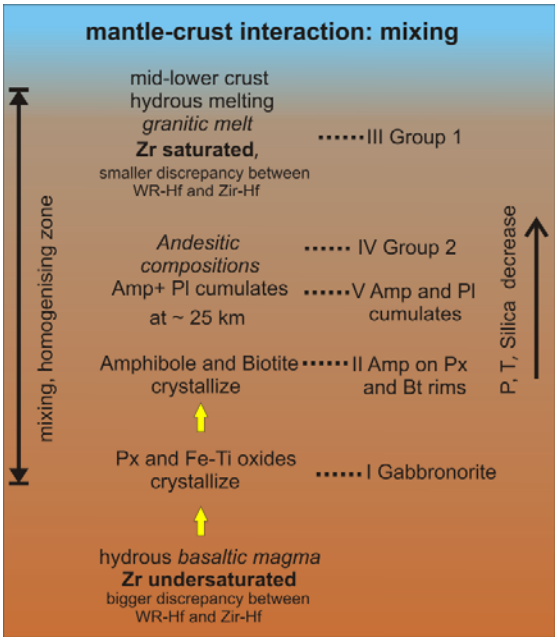

Fig. 6.9. Carton showing the mixing and crystallization process where mantle-derived lithologyinteracts with the crustal melt. See details in the text. I: Px and Ilm start to crystallize from the evolved basaltic magma at ~ 950-1100 °C (gabbronorite QL10-26). II: Amp started to crystallize by replacing Px as rims and Bt due to the lower P-T conditions and interaction with granitic melts at stage III. III: granitic melts (Group 1) by hydrous partial melting of mid-lower crust due to the basaltic magma (I) underplating. IV: hybrid andesitic magma (Group 2) of mantle lithology (part of QL10-26) and crustal melt (Group 1). V: Amp and Pl cumulated from the hybrids (Group 2).

Note that MMEs and Group 2 have overlapping Nd-Hf isotopes, indicating that MMEs were cumulates from the same magma systems as Group 2. As discussed above and based on the experiments (Grove et al., 2003; Bogaerts et al., 2006; Müntener and Ulmer, 2006), the possible crystallization order and relationship among the samples could be illustrated in Fig. 6.9. At higher temperature, the pyroxene and Fe-Ti oxides start crystallization from basalt at deeper level (QL10-26) (Fig. 6.9I). These assemblages were brought up to the shallower level, become unstable and start to crystallize amphibole and biotite due to the lower pressure and temperature (Fig. 6.9II) and also the interaction with felsic melt (Group 1). When the felsic melt homogenizing with solid mafic minerals, the hybrids reached intermediate andesitic composition at some point (Group 2). MMEs consisting of Amp and Pl (Fig. 6.9V) cumulated from this hybrid (Fig. 6.9IV). At each stage, Ti-rich minerals, e.g. Fe-Ti oxides, Px, Amp and Bt always crystallize relatively earlier at a higher temperature from a more mafic composition than Qz, Pl, Kfs and specially zircon. Therefore, their isotopes are always closer to the mafic endmember while the zircon only record hybrid isotopes with significant contributions from the felsic endmember. Different crystallization timing of different minerals results in the discrepancy between Zir-Hf and WR-Hf isotopes.

6.8. Magma generation and continental crust growth

The NQOB is an oceanic suture zone (Song et al., 2013). The oceanic basin, which was initially a back-arc basin induced by the subduction of Qilian Oceanic crust along the NQ-UHPM belt, may have started spreading since 710 Ma (Chapter 4). The tectonic evolution model is debatable in the NQOB (Yang et al., 2002; Wu et al., 2006a; Xu et al., 2006; Song et al., 2013; Chapter 4), but the Kekeli batholith along the southern margin of the NQOB is agreed to be subduction related (Song et al., 2013; Wu et al., 2010). The mafic component in QL10-26 is highly evolved basaltic melt from the partial melting of the mantle wedge due to slab dehydration. The small positive Pb and negative Ti anomalies result from the contributions of slab and crustal melts. We speculate that there is a mantle source beneath Qilian which the basalt originated from has decoupled Hf and Nd isotopes.

Based on the previous research, the decoupling maybe caused by the metasomatism (Salters and Hart, 1991; Salters and Zindler, 1995), the ancient melt depletion (Salters and Zindler, 1995), subduction zone process (Woodhead et al., 2001; Polat and Münker, 2004) and inherited garnet effect in the sources (Vervoort et al., 2000). In this study, we do not wish to discuss the detailed reasoning of Nd-Hf isotopes decoupling in the mantle wedge based on only one sample QL10-26, but suggest that radiogenic Hf isotopes must be from an ancient event.

The mantle-derived magma in the convergent zone ascends beneath the shallower crustal levels may have several effects: (1) release the fluids due to the lower water solubility with decompression (Moore et al., 1995; Papale, 1997) and the fluids lower the solidus of the crustal rocks; (2) heat the crustal rocks to solidus and mix with the derivative crustal melts. The melting of pelites and greywacks in the mid-lower crust begins at P-T of ~ 0.8GPa and ~750°C in response to influx of aqueous fluid and produce the peraluminous granitic melt (Brown, 2013), which corresponds to our Group 1 peraluminous samples with negative ε_{Nd} , ε_{Hf} and radiogenic $I_{Sr.}$ The temperature of 750 °C is also consistent with Ti-in-zircon thermometer (~780 °C) for Group 1 samples and easily achieved because the evolved basalts has high temperature 1100 °C (Dick et al., 2000; Niu et al., 2002). However, hornblende and plagioclase (MMEs) in hybrids Group 2 start cumulating at 0.8 GPa at 850 °C according to the hydrous arc magma experiments (H_2O> 4 wt%) (Grove et al., 2003; Müntener and Ulmer, 2006), which implies that the temperature before mixing was significantly higher. The whole rock suite in Kekeli batholith records the snap-shot of the magma interaction between mantle-derived melt and crustal melt in the subduction zone at ~ 500 Ma, including the ascent of mafic magma, hydrous melting of continental lower crust and mixing process as well as the mineral segregation from the andesitic hybrids in the magma chamber.

The amphibole-rich layer in the lower arc crust is considered to be the significant evidence of amphibole fractionation in the generation of the bulk andesitic continental crust in the arc magma evolution (Cawthorn and O'Hara, 1976; Moore and Carmichael, 1998; Davidson et al., 2007;

Hidalgo and Rooney, 2010). In our study, both the MMEs and Group 2 have neutral $\varepsilon_{Hf}(t)$ (>0) and $\varepsilon_{Nd}(t)$ (~ 0) (Fig. 6.6A,B). Trace element compositions of the host Group 2 are very similar to bulk continental crust (BCC) (Fig. 6.4). It is interesting to evaluate the role of the Amp+Pl bearing cumulates in the evolution of Kekeli batholith. Do they drive the magma composition from basaltic andesite to andesitic? Or do they essentially precipitate from the andesitic composition? The overlapping Nd and Hf isotopes between MMEs and host rocks indicate that the former precipitated from their hybrid andesitic host Group 2, therefore, they are essentially indirect products of the mixing process rather than the driving force to make basaltic arc magma evolve towards andesitic composition. In this case, these MMEs are not contributing to the andesitic magma generation. This concept is misleading but important in the context of the continental crust growth. For example, if we had only sampled Group 2 and MMEs, the possible interpretation would possibly be juvenile continental crust (Group 2) was produced by the amphibole fractionation (MMEs) from the basaltic arc magma based on all the geochemical data. Amp-bearing cumulates in the lower arc crust may play an important role in the arc magma evolution but not all of them have the same origin, therefore, it needs to be carefully interpreted.

6.9. Conclusions

Ti-rich minerals host abundant Hf too, especially in the more mafic lithologies. Zircon in situ Hf isotopes do not necessarily represent the whole-rock Hf isotope during magma mixing of two isotopically different sources, but only record the Hf isotopic composition closer to the felsic endmember at the time of zircon crystallization due to saturation. Ti-rich minerals, e.g. Fe-Ti oxides, Px, Amp and Bt, record the Hf isotope closer to the mafic endmember due to their early crystallization from a basaltic matrix. Generally, the early crystallization of Ti-rich minerals and later zircon crystallization causes the discrepancy between WR-Hf and Zir-Hf.

Kekeli batholith preserves the ascent of the mafic magma, interaction between mantle-derived melt and crustal melt as well as the mineral segregation from the hybrid andesitic magma in the subduction zone at ~ 500 Ma in the North Qilian Orogenic belt.

Chapter 7: Conclusions and future work

This thesis investigated the crustal growth on the Northern Tibetan Plateau, sampled as granitoids from the East Kunlun Orogenic Belt, the Qilian Block and the North Qilian Orogenic Belt. All the tectonic histories of these orogenic belts are quite debatable largely due to that people only see part of the picture. And I am not exceptional. The following chapter is to succinctly conclude the previous four chapters in order to address the aims presented in Chapter 1 and provide suggested directions for the future work.

7.1. The East Kunlun Orogenic Belt (Chapter 3)

Early Triassic syn-collisional granitoids with mafic magmatic enclaves (MMEs) crop out along the entire East Kunlun Orogenic belt (EKOB) at the northern margin of the Tibetan Plateau. They are andesitic in composition and enriched in light rare earth elements (LREEs) with a flat heavy REE (HREE) pattern. Their average composition resembles that of the bulk continental crust. The enclosed MMEs have the same mineralogy as their host granitoids, but contain a greater mode of mafic minerals (amphibole and biotite), and thus have higher HREE abundances. Zircon U–Pb dating shows that both the granitoid hosts and MMEs have the same crystallization age of ~ 250 Ma and indistinguishable bulk rock Sr–Nd–Pb–Hf isotope compositions (I_{Sr} of 0.7080–0.7116, varying $^{206}Pb/^{204}Pb_i$ of 18.53–19.32, essentially constant $\varepsilon_{Nd(t)}$ of -5.3 to -2.1 and a small range of positive $\varepsilon_{Hf}(t)$, mostly 1.7–5.2). The complete isotopic overlapping between the granitoid hosts and the MMEs is understood to reflect that the MMEs are disintegrated cumulates formed at an early stage of the granitoid magma evolution within the same magmatic system. The isotopic data set reveals that the granitoids are variably evolved melts produced by partial melting of the subducted Paleo-Tethyan oceanic crust with terrigenous sediments under amphibolite-facies conditions in response to the continental collision.

7.2. The Qilian Orogenic Belt

The Paleozoic granitoids in the Qilian Block are important for understanding the tectonic evolution of the Northern Tibetan Plateau. We choose granitoids from the Huangyuan (HY) and Gangcha (Gcha) areas for a detailed study.

7.2.1. The Qilian Block (Chapter 4)

The granitoids are both 'S-type' and 'I-type', and record different geological events from the Neoproterozoic to the Paleozoic. Most samples studied have an emplacement age of ~ 450 Ma with three samples being significantly older (924 Ma, 797 Ma and 503 Ma vs. 450 Ma). The ~ 924 Ma and ~ 797 Ma magmatism record events of crustal growth and crustal reworking, respectively. The 503 Ma plagiogranite-like granite contains mantle isotope signatures, probably resulting from extensive fractional crystallization of mantle-derived melt in a back-arc setting. The majority of the ~ 450 Ma granitoids have varying chemical compositions, but most of them share similar trace element patterns resembling the bulk continental crust composition. Despite their large compositional and age variations, significant correlations on Harker diagrams and in isotope spaces are consistent with their being different products essentially derived from common sources. The significant mantle contributions (70% ~ 80%, apart from QL09-02) required by whole rock Sr-Nd-Pb-Hf isotope data strongly suggest the mostly likely "mantle source" being last fragments of the subducted/underthrusting oceanic crust at the onset of collision. Despite some 'S-type' composition of the 450 Ma granitoids, the isotopes indicate that they represent crust growth in a syn-collisional setting. Based on all the petrology, geochronology, geochemical data and adjacent tectonic associations, we suggest that the Qilian Ocean started opening in the Neoproterozoic between the Qaidam Block and the Qilian Block. A back-arc basin was developed between the Qilian Block and the Alashan Block shortly after. The 450 Ma granitoids are the products in response to the closure of the Qilian Ocean and the onset of the Qilian-Qaidam continental collision.

7.2.2. The Qilian Block (Chapter 5)

The Qilian Block within the Qilian Orogenic belt on the northern Tibetan Plateau contains the contemporaneous two-mica granite from Huangyuan (HY) pluton and biotite-granite from Gangcha (Gcha) pluton of ~450 Ma. These granitoids provide useful information on the tectonic evolution of the Qilian Orogenic Belt. Here we present a geochronological and multi-isotopic study on these granitoids from the Qilian Block. Together with the literature data, we found that the Gcha pluton slightly predate the HY pluton. Zircon *in situ* Hf isotopes show much smaller variations for Gcha rocks than for the HY pluton. They have continuous concordant ages spreading from 510 Ma to 440 Ma. These characters are best explained by the magmatism since the onset of the collision at ~500 Ma, following slab steepening and the ultimate slab breakoff at ~450 Ma. Zircon Hf isotopes cover the same range but have different distribution patterns for Gcha and HY plutons, reflecting of the leading edge of the Qaidam continental lithosphere beneath the overriding Qilian plate.

7.2.3. The North Qilian Orogenic belt (Chapter 6)

The Kekeli Batholith in the North Qilian Orogenic Belt contains abundant cumulate assemblages dominated by amphibole and plagioclase plus minor other felsic minerals. There is a significant discrepancy between the whole rock Hf (WR-Hf) isotopes and *in situ* zircon Hf (Zir-Hf) isotopes, which demonstrates that (1) Zir-Hf isotope composition does not necessarily represent WR-Hf composition, and (2) zircon is not the sole major host of Hf. The positive correlation between WR-Hf isotope and TiO_2 indicates that the TiO_2-rich minerals are important Hf host apart from zircons. This correlation combined with the broad negative correlations between both ε_{Nd} and ε_{Hf} and silica further constrain that Kekeli batholith suites are the hybrids of mixing. The discrepancy between WR-Hf and Zir-Hf isotope composition can be explained by different crystalline timing of different minerals during magma mixing, Ti-rich minerals such as Fe-Ti oxides, Pyroxene (Px), amphibole (Amp), biotite (Bt) etc. crystallize earlier from the more mafic composition and preserve the isotope signature closer to the mafic endmember. In our case, zircons do not crystallize until the later stage when the hybrid magma reaches Zr saturation. Therefore, zircons generally record isotope

compositions closer to the felsic endmember. The gabbronorite QL10-26 has the highest TiO_2, the most radiogenic WR-Hf ($\varepsilon_{Hf}(t) = 26$) and contains pyroxene with Amp reaction rims, therefore close to the most depleted endmember. The peraluminous Group 1 granite samples have the lowest $\varepsilon_{Hf}(t)$ and $\varepsilon_{Nd}(t)$ and thus represent the crustal endmember. Group 2 samples with intermediate andesitic compositions between these two endmembers also have the intermediate isotopic compositions in between. The cumulates enclosed in Group 2 have overlapping isotopes with Group 2 and are interpreted to precipitate from Group 2. All these observations are consistent with the scenario that the mantle-derived magma underplated the mid-lower crust and mixed with the crustal melt by hydrous partial melting of the mid-lower crust accompanying the coeval metamorphism.

7.3. Problems and Future work

The importance of more work in the Qilian Block is demonstrated by the contrasting stories proposed by Chapter 4 and Chapter 5 respectively. A detailed work (e.g. higher resolution analysis) on the continuous age spread along the Concordia is certainly required. This common age spread both in metamorphic rocks and igneous lithologies is a key element and major hindrance to understand the ~450 Ma magmatism and the tectonic evolution in the area. As for the discrepancy between whole rock Hf and zircon *in situ* Hf isotopes discussed in Chapter 6, the most straight forward way is to analysis Hf isotope for all the Ti-rich minerals, especially ilmenite.

In Chapter 3 and 4, we have demonstrated that collision zone is a reasonable site to produce the granitoids which resemble the bulk continental crust (BCC) and can explain some features of the BCC which cannot be explained by the 'Island arc' model. However, the collision model invokes partial melting of the trapped subducted oceanic crust at 40 km underneath the overlying continental crust. The crustal thickness at the initiation of collision is major concern of the collision model because it controls the partial melting depth which in turn determines the composition of derivative magma. We do not know the crust thickness in the Kunlun orogenic belt ~250 Ma ago and Qilian Orogenic belt ~450 Ma ago, but it is no doubt that the continental crust in Andes or Tibet collision

zones had been significantly thickened, e.g. >50 km (Beck et al., 1996; Holt and Wallace, 1990; Mo et al., 2007). The following concern is that if the continental crust had been significant thickened > 50 km, is it possible for the subducting slab to underthrust into the depth of 40 km which is still within the lower crust? In other words, if the overriding continental crust was thicker than 50 km, partial melting of the subducting hydrous slab accommodated underneath would be beyond the amphibolite-facies field. Would the derivative melt capture an adakitic signature and would it still resemble the BCC composition? And the concern comes from the significantly thickened crust in Andes and Tibet. The concern about crust thickness is reasonable but may not be necessary. Mo et al (2007) proposed that the dominant tectonically compression and crustal shortening in Tibet happened ~ 10 Ma after the initiation of the collision and only contribute 20 km thickness. On the contrast, the syn-collisional magmatism before the tectonically shortening and thickening contributes 30% of the total thickness of the present-day Tibetan crust. If this is the case, it means that the crust thickening results from the syn-collisional magmatism rather than the other way round. Importantly, it means that the crust thickness at the initiation of the collision remained normal, e.g. ~35 km, and it is not problematic for the subducting slab to partial melt at ~40 km. Besides, in chapter 3, an important proof of the collision at 250 Ma is the unconformity between the upper-Permian to lower-Triassic marine strata and lower Permian terrestrial strata, implying that the overlying continental plate had been above sea level at the late Permian and the crust probably had thickened, in which case, the crust thickness probably thicker than 40 km. However, there is a large uncertainty in this unconformity as the strata have not been precisely dated but only from the simple field observation. Obviously, the accurate age data for this unconformity would very much help conclude Chapter 3.

In the collision model, the subducting slab is considered as the source of the granitoids because it is basaltic and carries mantle isotopic composition. One may argue that, the subducted island arc could be the source as well. In Chapter 4, we simply mentioned that the island arc crust is

topographically high level and is too cold to melt. We would like to extend the discussion a bit more here. First of all, the Kunlun and Qilian Orogenic belts are both considered as the continental margins. It is not likely to develop island arc there. Secondly, even if there was island arc, their isotopic composition should be similar to the oceanic crust. Partial melting of the quickly recycled island arc would only enhance the 'arc' signatures in the derivative melt, which is difficult to be distinguished from the slab-derived melt in the collision zone. In this case, we take the overall products as the slab-derived melt. Additionally, reworking of the continental arcs may play a role in the syn-collision magmatism as discussed in Chapter 4. But reworking of continental arc alone cannot explain the large compositional variations in the Qilian Block granitoids and especially, cannot explain the dominant andesitic compositions in the East Kunlun Batholiths which require a more mafic source (basaltic andesite or basalt).

Arguments against collision model also arise from decompression melting of the exhumated oceanic eclogites. These eclogites carry mantle isotopes and they are basaltic too. However, partial melting of them would produce the melt with adakite signature because garnet is the residual phase preferentially hosting HREEs than LREEs. In Qilian Orogenic belt, decompression melting of the eclogites has indeed been observed and its derivative melt is adakitic (Song et al., 2014) while our granitoids do not have adakite signature. Another important thing to end this debate is to precisely constrain the exhumation of the eclogites. In the Qilian Orogenic belt, the timing of the eclogite exhumation is still controversial. Song et al., (2013) suggest that the exhumation happened at ~ 420 Ma while Xu et al. (2006) proposed that the exhumation began at 470 – 460 Ma. Maybe it is a bit too early to say that the granitoids in Chapter 4 were produced in a syn-collisional setting before we can place more constrains on the metamorphic rocks.

In the published Chapter 3, Songpai-Ganzi has been considered as a continental plate on the subducting side. However, some study suggest that Songpai-Ganzi is a huge accretionary prism (Yin and Harrison, 2000). If this is the case, the proper continental plate would be Qiangtang block

further south in the Tibetan Plateau (Yin and Harrison, 2000). But this change would not affect the theme of Chapter 3 nor collision model.

Bottom of line, the whole rock Sr-Nd-Hf-Pb isotopes were employed throughout the course of this study. Using these isotopes to trace the source of basalts is straight forward because the mineral assemblage is relatively simple in the mantle. However, as to the granitoids which are largely produced at the crustal level, more factors need to be taken into account, e.g. disequilibrium melting. The isotopic heterogeneities of the granitoids have generally been attributed to the inheritance from the source. But experiments and field observations have shown that partial melting at crust level is generally non-modal and produces melts with isotopic compositions in disequilibrium with respect to their sources (Harrison and Watson, 1984; Harris, et al., 1995; Knesel and Davidson, 2002; Zeng et al., 2005). Crust contains various mineral phases which could easily develop isotopic disequilibrium. For example, garnet has large Lu/Hf ratio and would be radiogenic in Hf isotopes with time. Biotite has high Rb/Sr ratio and would possess relatively high-time integrated $^{87}Sr/^{86}Sr$ ratio. Other accessory phases, such as zircon, apatite, ilmenite, and monazite also play an important role in controlling the distribution of trace elements and producing the isotopic disequilibrium. Whether the isotopic heterogeneities and the decoupling between Nd and Hf isotopes is related to the partial melting of crustal lithologies whose mineral phases have developed disequilibrium has not been investigated in this study. Future work on this subject is highly recommended.

Table 3.4 Whole rock Sr isotopic data. The last column refers to the analytical session during which the sample was analysed for Sr isotope composition. The blank, the average $^{87}Sr/^{86}Sr$ and reproducibility of multiple measurements of the NBS987 Sr isotope standard during the appropriate session are given below:

1: 0.710267±01 (2SD, n=13), blank=8 pg

2: 0.710283±02(2SD, n=8), blank=23 pg

3: 0.710284±05(2SD, n=9), blank=24 pg

$^{87}Sr/^{86}Sr$ are reported relative to an accepted $^{87}Sr/^{86}Sr$ ratio for NBS987 of 0.71024 (Thirlwall, 1991)

Sample	Type	Rb(ppm)	Sr(ppm)	$^{87}Rb/^{86}Sr$	$^{87}Sr/^{86}Sr$(2SD)	I_{sr}	Analytical sessions

Table 4.5 Whole rock Sr-Nd-Pb-Hf isotopic data.The subscribe refers to the analytical session during which the sample was analysed for isotopic compositions. The averages and reproducibility of multiple measurements of the isotope standards during the appropriate sessions are given below:

1: JMC475, 0.282160±08 (2SD, n=10); 2: 0.282160±06 (2SD, n=12). $^{176}Hf/^{177}Hf$ are reported relative to an accepted ratio for JMC475 of 0.282160 (Nowell et al., 1998)

3: J&M, 0.511110±11 (2SD, n=19); 4: 0.511110±07 (2SD, n=11). $^{143}Nd/^{144}Nd$ are reported relative to an accepted ratio for J&M of 0.511110 (Thirlwall, 1991)

5: NBS987, 0.710267±10 (2SD, n=13); 6: 0.710277±15(2SD, n=9). $^{87}Sr/^{86}Sr$ are reported relative to an accepted $^{87}Sr/^{86}Sr$ ratio for NBS987 of 0.71024 (Thirlwall, 1991)

7: NBS981, $^{206}Pb/^{204}Pb$:16.94102±184; $^{207}Pb/^{204}Pb$:15.49811±142; $^{208}Pb/^{204}Pb$:36.71791±512 (2SD, n=11)

8: NBS981, $^{206}Pb/^{204}Pb$:16.94083±274; $^{207}Pb/^{204}Pb$:15.49706±115; $^{208}Pb/^{204}Pb$:36.71478±399 (2SD, n=16)

Table 5.2 Whole rock Sr-Nd-Pb-Hf isotopic data.The subscribe refers to the analytical session during which the sample was analysed for isotopic compositions. The averages and reproducibility of multiple measurements of the isotope standards during the appropriate sessions are given below:

1: JMC475, 0.282160±08 (2SD, n=10); 2: 0.282160±06 (2SD, n=12). $^{176}Hf/^{177}Hf$ are reported relative to an accepted ratio for JMC475 of 0.282160 (Nowell et al., 1998)

3: J&M, 0.511110±11 (2SD, n=19); 4: 0.511110±07 (2SD, n=11). $^{143}Nd/^{144}Nd$ are reported relative to an accepted ratio for J&M of 0.511110 (Thirlwall, 1991)

5: NBS987, 0.710267±10 (2SD, n=13); 6: 0.710277±15(2SD, n=9). $^{87}Sr/^{86}Sr$ are reported relative to an accepted $^{87}Sr/^{86}Sr$ ratio for NBS987 of 0.71024 (Thirlwall, 1991)

7: NBS981, $^{206}Pb/^{204}Pb$:16.94102±184;$^{207}Pb/^{204}Pb$:15.49811±142;$^{208}Pb/^{204}Pb$:36.71791±512 (2SD, n=11)

8: NBS981, $^{206}Pb/^{204}Pb$:16.94083±274;$^{207}Pb/^{204}Pb$:15.49706±115;$^{208}Pb/^{204}Pb$:36.71478±399 (2SD, n=16)

$\varepsilon_{Hf}(t)$: Age corrected to zircon crystallization age.

The last two numbers in the first column refer to the same numbers in the zircon U-Pb ages analyzed in CUG in Table S1.

Table 5.4 Zircon in situ LA-ICP-MS dating results

	Pb	Th	U	Th/U	CORRECTED RATIOS						CORRECTED AGES (Ma)
